chemokine ligand 3 (CCL3), heat shock protein 70 kDa 1B (HSPA1B), interleukin-8 (IL-8), granzyme B (GZMB), and matrix metalloproteinase-8 (MMP8). The top node of the decision tree, the root node, provides the total number of subjects, as well as the number and proportion of survivors and non-survivors (28-day all-cause mortality). Subjects in the root node are subsequently allocated to daughter nodes on the basis of the results of binary recursive partitioning. Each daughter node provides the criterion for deciding subsequent partitions, along with the number and proportion of survivors and nonsurvivors. All biomarker concentrations are in pg/mL. Terminal nodes (TNs) reflect the final assignment of risk to an individual case. Terminal nodes are considered low risk (mortality probability 0.0–0.02; TN2, TN5, and TN8), intermediate risk (mortality probability 0.18–0.27; TN1, TN3, and TN6), or high risk (mortality probability 0.47–0.63; TN4 and TN7).

A temporal version of PERSEVERE measured the biomarkers over time and how the biomarker changes reflect changing probability of poor outcome risk.[180] A version of PERSEVERE has also been developed for adults with sepsis, which is called ASSIST (Adult Septic Shock Information and Stratification Technology).[181] Both PERSEVERE and ASSIST outperform currently used mortality risk prediction tools.[183]

Several applications are possible for PERSEVERE. These include stratification for clinical trial enrollment, serving as a benchmark for quality improvement efforts, and informing individual patient decision making. Recently, PERSEVERE was used to conduct retrospective, stratified analyses of clinical data.[209,265]

Concluding Perspectives

Sepsis is and will continue to be an important challenge to the pediatric intensivist. Indeed, sepsis is one of the few disease processes for which the pediatric intensivist can claim “ownership.” Although much is known about the biological and molecular mechanisms involved in sepsis, much of this knowledge has not directly translated to improved bedside care. At present, most of the therapeutic modalities for sepsis are fundamentally supportive and founded on the basic principles that define the discipline of critical care medicine. Although this approach has directly improved the outcome of sepsis in children, the fact that more than 4000 children per year in the United States alone continue to die in association with severe sepsis warrants further advances. Realization of this goal is feasible but requires further mechanistic insights at the physiologic, molecular, and genetic levels, as well as the design of large-scale, pediatric-specific interventional trials complemented by evolving stratification strategies. As “owners” of pediatric septic shock, pediatric intensivists are well positioned to lead this effort on all fronts.

CHAPTER 112

Multiple Organ Dysfunction/Failure Syndrome in Children

Joseph A. Carcillo

PEARLS

- One view of the pathogenesis of multiple organ dysfunction/multiple organ failure syndrome (MODS/MOF) is uncontrolled systemic inflammation that leads to reversible epithelial, endothelial, and mitochondrial dysfunction.
- Three factors are required for systemic inflammation to produce MODS/MOF syndrome: (1) increased circulating pathogen-associated molecular pattern molecules (PAMPS; endotoxin or microbial products), (2) increased circulating danger/damage-associated molecular pattern molecules (DAMPS; necrotic cell constituents), and (3) defective host metabolism (reduced cytochrome P-450, mitochondrial activity).
- MODS/MOF syndrome has been classified as primary (when occurring in the first 7 days of illness) and secondary (when commencing after 7 days). Ninety percent of patients have MODS/MOF at presentation to the pediatric ICU, whereas 10% develop sequential MOF over time with liver and renal involvement following initial lung dysfunction.
- Three or more organ failures at admission are associated with higher mortality (25%) than fewer than three (2%). Resolution of three organ failures to fewer than three by day 3 is associated with 8% mortality compared with 35% mortality in children for whom three or more organ failure persists beyond day 3. Both degree of systemic inflammation and mortality increase as the number of organs failing increases.
- Timely source control (removal of the inflammation source using appropriate antibiotics for infections and necrotic tissue nidus removal for trauma-driven injury) and reversal of shock/ischemia prevent the development of MODS/MOF.
- Persistent or progressive MODS/MOF can be viewed as a spectrum of inflammation phenotypes that can respond to personalized therapies when source control and shock reversal are achieved. These include (1)

thrombocytopenia-associated MOF (TAMOF, thrombotic microangiopathy); (2) immune paralysis/lymphoid depletion syndrome (predominant TH_2 phenotype); (3) viral/lymphoproliferative disorder–associated sequential MOF (natural killer [NK] cell/cytotoxic T-cell/B-cell/T-regulatory cell dysfunction); (4) iron overload cardiac/hepatic/pancreatic MOF (secondary hemochromatosis); (5) hyperleukocytosis MOF (pertussis leukocyte proliferating factor); and (6) the end pathway of uncontrolled inflammation from any phenotype, macrophage activation syndrome.

- Responses are as follows: (1) TAMOF and thrombotic microangiopathy respond to plasma exchange and the C5A antibody eculizumab; (2) immune paralysis/lymphoid depletion syndrome (predominant TH_2 phenotype) responds to immune suppressant withdrawal and granulocyte-macrophage colony-stimulating factor; (3) viral/lymphoproliferative disorder–associated sequential MOF (natural killer [NK] cell/cytotoxic T-cell/B-cell/T-regulatory cell dysfunction responds to intravenous immunoglobulin (IVIG) and in the case of EBV infection, the CD20 antibody rituximab); (4) iron overload cardiac/hepatic/pancreatic MOF (secondary hemochromatosis) responds to iron chelation therapy; (5) hyperleukocytosis MOF (pertussis leukocyte proliferating factor) responds to leukoreduction therapy; and (6) the end pathway of uncontrolled inflammation from any of these phenotypes, macrophage activation syndrome, responds to methylprednisone, IVIG, plasma exchange, and the IL-1 receptor antagonist, anakinra.

Introduction

Systemic inflammation caused by trauma, pancreatitis, burns, or shock can lead to the *systemic inflammatory response syndrome* (SIRS). When caused by infection, the sepsis syndrome is recognized and defined by the presence of two of four criteria: tachycardia, tachypnea, fever, and abnormal white blood cell count (Fig. 112.1). If uncontrolled, increased systemic inflammation from tissue injury and/or infection leads to the *compensatory antiinflammatory response syndrome* (CARS) (Fig. 112.2), which further mediates severe SIRS/sepsis (SIRS/sepsis + one-organ failure) and ultimately *immunologic dissonance,* with the development of multiple-organ failure (Fig. 112.3). The multiple organ dysfunction (MOD)/multiple organ failure (MOF) syndrome is recognized by the clinician after clinical documentation of cardiovascular, respiratory, hepatic, renal, hematologic, and central nervous dysfunction. Multiple organs are affected when uncontrolled inflammation induces systemic epithelial, immune, and endothelial cell dysfunction.

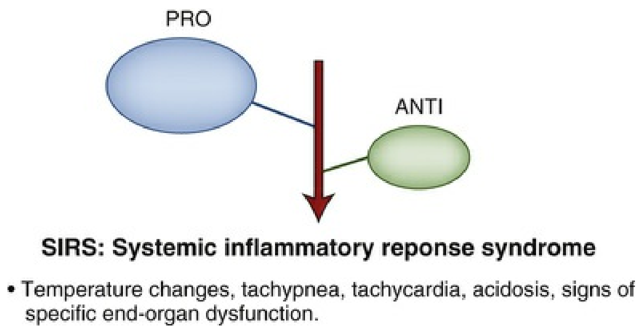

FIG. 112.1 Systemic inflammatory response syndrome.

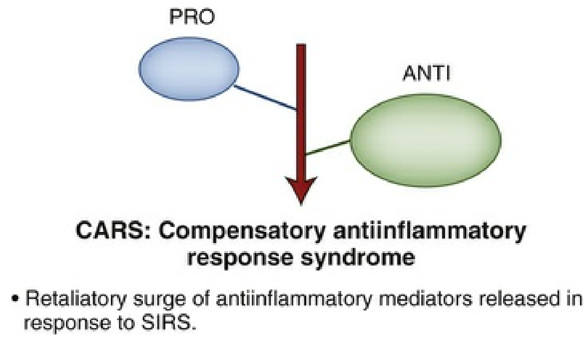

FIG. 112.2 Compensatory antiinflammatory response syndrome.

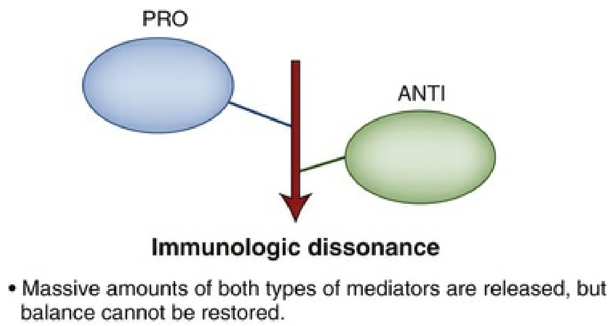

FIG. 112.3 Immunologic dissonance. (From Bone RC. Immunologic dissonance: a continuing evolution in our understanding of the systemic inflammatory response syndrome [SIRS] and the multiple organ dysfunction syndrome [MODS]. Ann Intern Med. 1996;125:680-687.)

Inflammation/Coagulation/Immune Dysfunction/Dysregulated Metabolism Hypothesis

Roger Bone popularized the notion that systemic inflammation led to the development of multiple organ failure in the 1990s. According to this theory, an initial proinflammatory cytokine response to foreign or self-antigen caused SIRS, which is characterized by two of four criteria including tachycardia, tachypnea,

fever, and leukocytosis (see Fig. 112.1). This syndrome was thought to be mediated by increased IL-1 and tumor necrosis factor alpha (TNFα) levels (Fig. 112.4). It could be blunted by nonsteroidal antiinflammatory drugs (NSAIDs) and hence was thought to be mediated in part by prostaglandins. SIRS was called *sepsis* if related to infection and SIRS if related to surgery, pancreatitis, or other noninfectious processes. This syndrome was self-limited when antibiotics were used to kill the infection or time allowed recovery from surgery, pancreatitis, and other noninfectious causes of SIRS. This "proinflammatory response" was turned off by an antiinflammatory response led by the antiinflammatory cytokine IL-10. When IL-10 resulted in reduction of IL-1 and TNFα to normal control values, sepsis or SIRS stopped and organ failure did not occur. In patients who developed severe sepsis and MOF, the *compensatory antiinflammatory response* (CARS) was unsuccessful in turning off inflammation (see Fig. 112.2). Instead, these patients had persistent elevation of the cytokine IL-6 along with IL-10. Dr. Bone coined the term "immunologic dissonance" to describe this process. He viewed MOF as an inflammatory condition in which the normal antiinflammatory response was unable to turn off the proinflammatory process (see Fig. 112.3).

FIG. 112.4 Infection or necrotic tissue evokes a proinflammatory cytokine response that brings blood flow to the site of infection. *IL-6*, interleukin 6; *IL-1*, interleukin 1; *LPS*, lipopolysaccharide; *NO*, nitric oxide; *TNFα*, tumor necrosis factor alpha.

Proulx et al.[1] defined pediatric MOF syndrome as being primary and secondary. Primary MOF occurred in 90% of children and was present at the time of admission, and secondary MOF occurred in 10% of children and was not present until 7 days after admission.[1] To evaluate the role of inflammation in pediatric sepsis-induced MOF, the authors defined children as having no MOF (or NMOF) if they had two-organ failure at presentation but never reached three-organ failure, resolved MOF (or RMOF) if they had three-organ failure at admission that resolved to two or fewer at 48 hours, persistent MOF (or PMOF) if they had three-or-more organ failure at presentation that did not resolve by 48 hours, and sequential MOF (or SMOF) if they had acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) at admission and then progressed to have hepatorenal failure/dysfunction.[2] Similar to Dr. Proulx's classification, children in the latter investigation with SMOF represented 10% of the population. The mortality rates with NMOF, RMOF, PMOF, and SMOF were 2%, 8%, 35%, and 50%, respectively. The authors then investigated Dr. Bone's hypothesis within these categories and reported that patients with NMOF had an increase in IL-10 with subsequent turning off of inflammation; however, those with PMOF or SMOF had persistently high IL-6 and IL-10 levels, the hallmark of immunologic dissonance.[2]

Dr. Bone's untimely demise prevented him from further pursuing the mechanisms by which immunologic dissonance could mediate organ injury. However, the

authors first reviewed the autopsy bank at their hospital and noted that children who died from sepsis-induced multiple organ failure exhibited two unsuspected findings compared with children who died of other causes: persistent or unrecognized infection and thrombotic and bleeding complications with organ infarctions (Figs. 112-5 and 112-6). Accordingly, the authors pursued the notion that immunologic dissonance might lead to an inability to mediate coagulation homeostasis, as well as an inability to clear infection. Proinflammatory cytokines including TNFα and IL-1 induce endothelial activation in vitro with an increased prothrombotic and antifibrinolytic state and expression of adhesion molecules (Fig. 112.7). Patients with PMOF had increased tissue factor and plasminogen activator-1 activity, as well as circulating adhesion molecules, ICAM and VCAM, consistent with the hypothesis that immunologic dissonance was associated with an activated prothrombotic/antifibrinolytic endothelium.[3,4] IL-6 also inhibits ADAMTS-13, the vWF multimer protease, in vitro. PMOF patients also had deficient ADAMTS-13 activity compared with NMOF patients, consistent with increased risk of vWF multimer–mediated thrombosis (Figs. 112.8 and 112.9).[5] Increased IL-10 is the hallmark of the TH_2 antiinflammatory cytokine response. When the TH_2 response is dominant, then the TH_1 response can be turned off, a state known as *immune paralysis* (Fig. 112.10). These patients have a diminished ex vivo ability to secrete TNFα from endotoxin-stimulated monocytes or macrophages. Without this ability, infections cannot be terminated. The PMOF patients exhibited immune paralysis more frequently than the NMOF patients.[6]

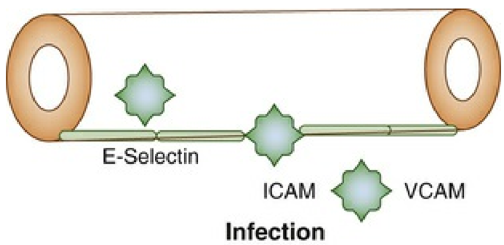

FIG. 112.5 The proinflammatory cytokines stimulate expression of adhesion molecules that allow immune cells to roll, stick, and then transmigrate to kill the infection. *E-selectin*, endothelial selectin; *ICAM*, intercellular adhesion molecule; *VCAM*, vascular cell adhesion molecule.

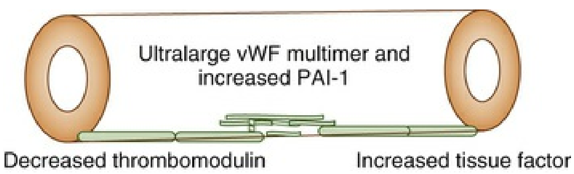

FIG. 112.6 The proinflammatory cytokines increase expression of prothrombotic molecules and decrease expression of antithrombotic molecules to seal off endothelium at the site of infection. After the infection is killed or necrotic cells are cleared, there is no longer a proinflammatory cytokine response. The endothelium returns to its usual antithrombotic, profibrinolytic state. *PAI-1*, plasminogen activator inhibitor–type 1; *vWF*, von Willebrand factor.

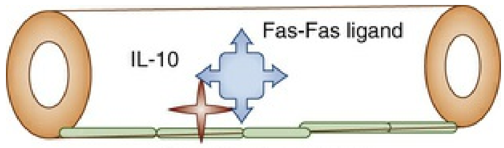

FIG. 112.7 After the infection is killed or necrotic cells are cleared, the antiinflammatory cytokines turn off expression of the proinflammatory cytokines. This results in reduction in monocyte/macrophage tumor necrosis factor production and apoptosis of activated immune cells.

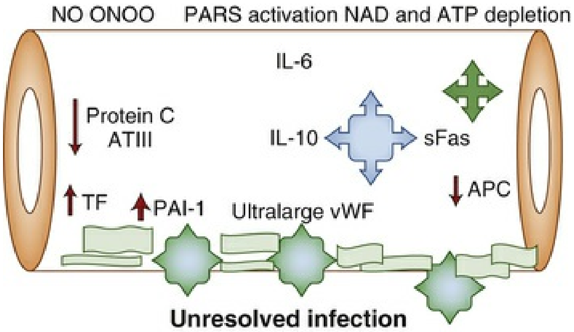

FIG. 112.8 In immunologic dissonance, multiple-organ-failure (MOF) patients are unable to resolve infection and inflammation. They remain in a prothrombotic/antifibrinolytic state with microvascular thrombosis and thrombocytopenia-associated MOF. They also have immune paralysis with ineffective antigen presenting cell activity mediated in part by increased IL-10. Sequential MOF can occur when increased sFasL levels >500 pg/mL induce liver injury. Metabolism is also adversely affected as nitric oxide + superoxide anion lead to the formation of peroxynitrite radicals that inhibit cytochrome P-450 activity and mitochondrial respiration. *APC,* antigen presenting cell; *AT III,* antithrombin III; *NO,* nitric oxide; *ONOO,* peroxynitrite; *PAI-1,* plasminogen activator inhibitor type 1; *PARS,* polyadenosylribose synthase; *TF,* tissue factor.

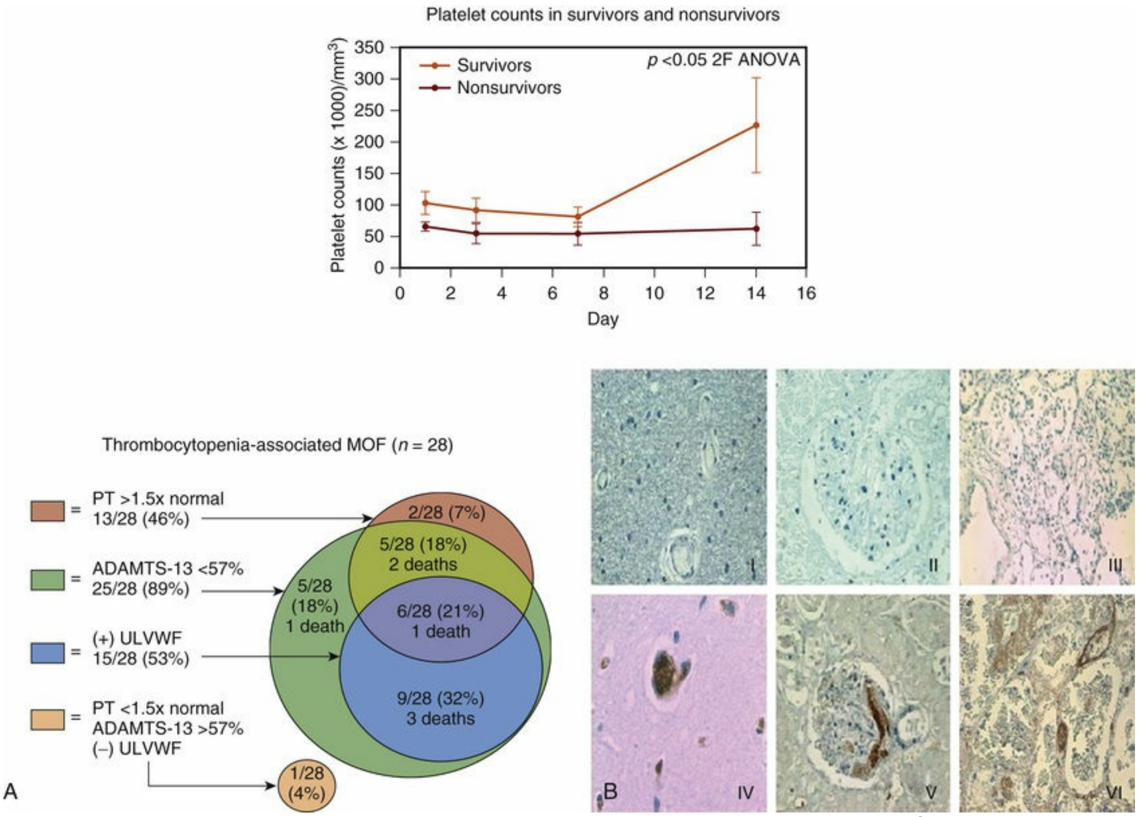

FIG. 112.9 Untreated thrombotic microangiopathy causes death from microvascular thrombosis. TAMOF is heralded by new-onset thrombocytopenia and MOF. Survivors recover their platelet count, whereas nonsurvivors do not. In this study 89% of these patients had reduced ADAMTS-13 (A). At autopsy patients had vWF multimer thrombi (B) in brain (IV), kidney (V), and lung (VI). These microthrombi can resolve with intensive plasma exchange therapy that removes thrombogenic ultralarge vWF multimers and replenishes ADAMTS-13 enzyme. (From Nguyen TC, Han YY, Kiss JE, et al. Intensive plasma exchange increases ADAMTS-13 activity and reverses organ dysfunction in children with thrombocytopenia-associated multiple organ failure. Crit Care Med. 2008;36:2878-2887.)

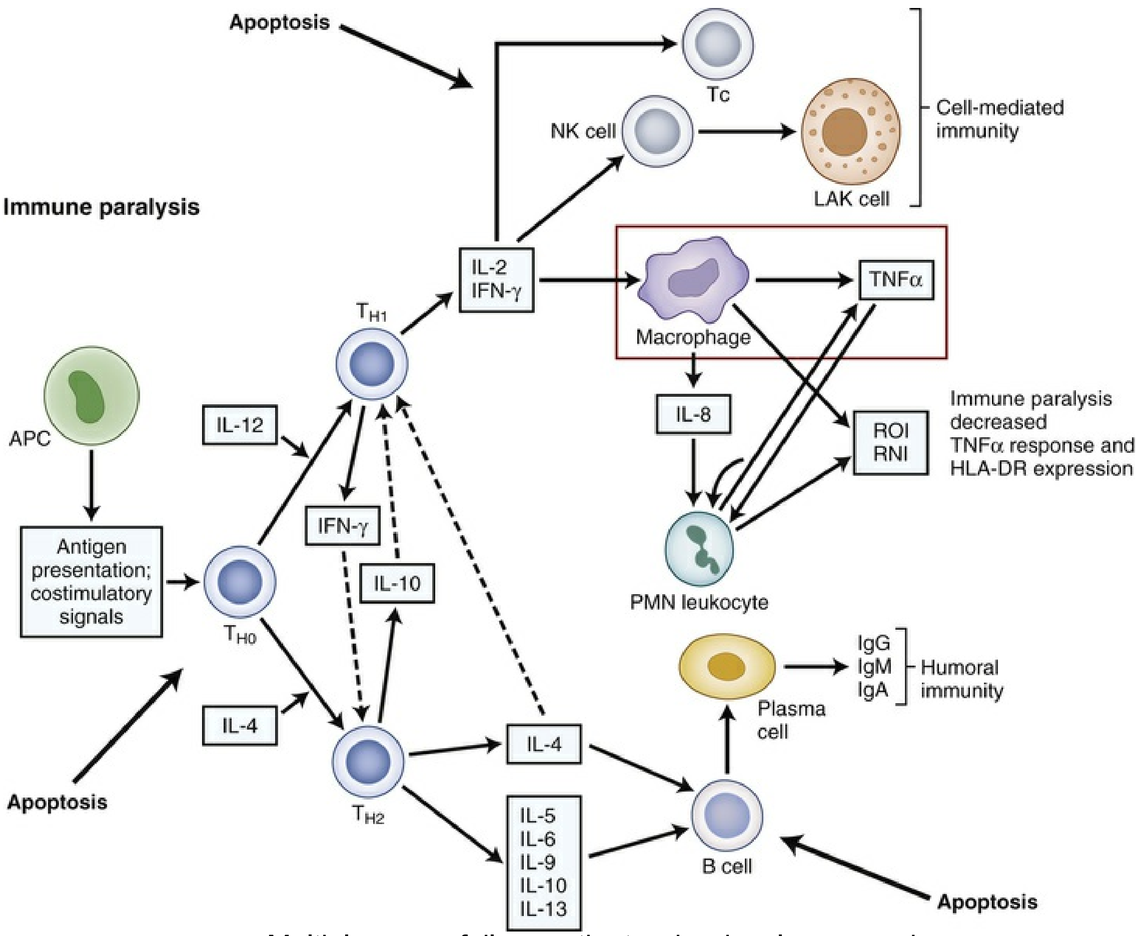

FIG. 112.10 Multiple-organ-failure patients who develop secondary infections commonly have immune paralysis with an ex vivo tumor necrosis factor alpha response to lipopolysaccharide <200 pg/mL and/or reduced monocyte human leukocyte antigen−antigen D-related expression <30% or <8000 molecules/cell. Immune function can be restored by stopping immunosuppressant therapy and by low-dose granulocyte-macrophage colony-stimulating factor therapy.

Cytokines and nitric oxide also inhibit cytochrome P-450 activity and mitochondrial respiration in vitro.[7,8] The authors found that patients with PMOF had reduced (10-fold) cytochrome P-450 activity compared with patients with NMOF (2-fold).[8] *Immunologic dissonance* in PMOF was associated with endotheliopathy, immune paralysis, and impaired P-450 metabolism, but how was PMOF different from SMOF? The authors determined that patients with SMOF were more likely to have viral or lymphoproliferative disease with high sFasL levels. In vitro, sFasL levels >500 pg/mL cause hepatocyte necrosis. Children with MOF with sFasL levels >500 pg/mL demonstrated liver injury at autopsy.[9] The mechanism of injury in SMOF was different from in patients who presented with MOF (see Figs. 112.5 and 112.6).

Over the past decade, investigators from the United Kingdom have investigated the inflammation/immune dysregulation hypothesis in SIRS/sepsis hypothesizing that dysregulated complement activity increases the risk of SIRS/sepsis.[10] Mannose-binding lectin (MBL) is an early-released complement activation component and is required for the first 12 hours of complement activity. Approximately 30% of children are MBL deficient. Complement factor H inhibits complement activity, and

factor H Y402H polymorphism reduces this complement inhibition activity. Using genotype analyses, these investigators have demonstrated that children at risk for SIRS/sepsis more commonly have deficiencies in MBL production and a reduction in this H factor polymorphism. Together, these two characteristics are associated with an even greater risk of SIRS/sepsis than either one alone. The interpretation is that diminished early complement (MBL) prevents rapid clearance of antigen leading to the SIRS/sepsis syndrome, but absence of inhibitory complement (CFH/CFI) prevents turning off systemic inflammation and is associated with the development of disseminated intravascular coagulation and MODS/MOF. Over the past decade, thrombocytopenia-associated MOF and atypical HUS/TTP have been linked to many genetic mutations related to reduced or even absent inhibitory complement production.[11] Accordingly, the inflammation hypothesis of MOF is alive and well.

Definitions and Scoring

As noted previously, SIRS is defined by two of the following four criteria: tachypnea, tachycardia, fever, and leukocytosis. Sepsis is defined as SIRS + suspected or documented infection. Severe sepsis is defined by sepsis + organ failure. MOF or MODS is defined by more-than-one-organ failure. Many definitions exist for defining organ failure. Wilkinson and Pollack published the first definitions in pediatrics that were subsequently modified by Proulx and then again by Doughty.[2,12] Goldstein, Giroir, and Randolph subsequently developed two more sets of definitions.[13] Doughty developed the organ failure index (OFI) to score organ failure.[2] It is a simple integer score that assigns 1 point for each organ failure. Leteurtre reported two more MOF scores, the PEMOD and PELOD scores.[14] The PEMOD score assigns 1 to 4 points per organ failure depending on severity. The PELOD score logistically weights these scores to hopefully allow for prognostication. Due to controversy concerning the use of the PELOD score in this manner, the authors have more recently developed the updated PELOD2 score.[15]

Outcomes

In the United States, survival in the setting of SIRS/sepsis is almost universal. Odetola et al.[16] reported that survival in severe sepsis is 96%, overall 98% in previously healthy children, and 92% in children with chronic diseases. Typpo et al.[17] reported that survival from MOF is 90%. Survival rates decrease as the number of organ failures increase.

MOF/MODS Phenotypes, Respective Biomarkers, and Therapies (Table 112.1)

Thrombocytopenia-Associated MOF

New-onset thrombocytopenia is a harbinger of thrombotic microangiopathy in MOF, especially when accompanied by increased lactate dehydrogenase (LDH) and reduced renal function. Until this decade, thrombotic microangiopathy of critical illness was thought to be mediated by fibrin, but more recent work suggests that von

Willebrand factor (vWF) multimers associated platelet thrombi are a previously unrecognized cause. If ADAMTS-13 concentration (vWF cleaving protease) is <57% of control and vWF multimer concentration is increased, then this form of thrombosis should be highly suspected (Figs. 112.8 and 112.9). Intensive plasma exchange can reverse this process because it removes the thrombogenic ultra-large vWF multimers and replenishes ADAMTS-13 vWF cleaving protease activity.[5,18] More recently, C5a monoclonal antibody (eculizumab) has been added to plasma exchange to treat TAMOF associated with atypical HUS/TTP.[19]

TABLE 112.1

Multiple-Organ-Failure (MOF) Phenotypes

Phenotype	Diagnosis	Therapy
Thrombocytopenia-associated MOF	New-onset thrombocytopenia and MOF with increased LDH and renal involvement ADAMTS-13 <57%	Intensive plasma exchange until resolution of TAMOF Eculizumab for atypical HUS/TTP form
Immune paralysis MOF	Whole blood TNFα response to LPS <200 pg/mL or monocyte HLA-DR expression <30% or <8000 molecules/cell for >3 days	Rapidly taper immunosuppressants Give low-dose GM-CSF at 5 ug/kg/day sc × 7 days
Sequential MOF	Respiratory then hepatorenal PTLD – EBV disease posttransplantation	Stop immunesuppressants; give rituximab + IVIG
Iron overload MOF	History of multiple transfusions. Ferritin >1000 pg/L, Fe binding >50%	Iron chelation, coverage for aspergillus during chelation
Hyperleukocytosis MOF	Pertussis + high white blood cell count + ARDS and pulmonary hypertension	Leukopheresis or whole blood exchange
Macrophage activation syndrome	Hepatobiliary dysfunction + disseminated intravascular coagulation + ferritin >500 ug/L	Methylprednisone, IVIG, plasma exchange, anakinra, and/or tocilizumab

ARDS, acute respiratory distress syndrome; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IVIG*, intravenous immunoglobulin; *LDH*, lactase dehydrogenase.

Immune Paralysis and Lymphoid Depletion Syndrome

Adult and neonatal investigators noted the association among lymphocyte apoptosis, lymphoid depletion, and death from nosocomial sepsis. When dendritic cells/monocytes/macrophages ingest lymphocytic apoptotic bodies, a profound TH_2 response ensues with immune paralysis and death associated with uneradicated infection (Fig. 112.10). Pediatric studies corroborate these findings with immune paralysis and prolonged lymphopenia associated with nosocomial infection and death.[6] In transplant patients, rapid tapering of immune suppressants can restore monocyte function and reverse immune paralysis. In non–immune-suppressed patients, low-dose subcutaneous granulocyte-macrophage colony-stimulating factor (GM-CSF) can reverse immune paralysis. If patients have hypogammaglobulinemia, IVIG can be given. If they are severely lymphopenic, then antimicrobial prophylaxis can be considered for affected patients. Clinical trials of PDL-1 ligand inhibitor (prevents innate immune cell phagocytosis of PD-1 expressing lymphocytes) and IL-7 (lymphocyte growth factor) are beginning with the goal of reversing lymphopenia (absolute lymphocyte count <1000/uL) in adults.

Viral/Lymphoproliferative Disease–Associated

Sequential or Liver-Associated MOF Syndrome

This MOF subset represents only 10% of MOF, but it carries the worse prognosis. Liver injury is associated with high sFasL levels >500 pg/mL.[9] In transplant patients the most common cause is posttransplant lymphoproliferative disease. Epstein-Barr virus (EBV) intercalates viral IL-10 genome into B cells, preventing activated immune cell death and promoting lymphoproliferation. This is treated by stopping immune suppression, giving the B-cell monoclonal antibody rituximab, and administering interferon-α if necessary. In nontransplant patients with a family history of a similar disease, X-linked immunoproliferative disease should be considered (XIAP). These patients cannot direct programmed cell death in activated immune cells and are treated with chemotherapy and bone marrow transplantation to kill activated immune cells and replenish functioning NK/cytotoxic T-lymphocyte (CTL) cells.

Secondary Hemochromatosis-Associated Cardiac Hepatopancreatic MOF

Patients who have received multiple blood transfusions (including patients with aplastic anemia, liver failure, and hemolytic anemias) develop iron overload with high ferritin >1000 ug/L and iron-binding capacity <50%. Iron deposition can be diagnosed by liver magnetic resonance imaging. Infections thrive with this excess iron environment, and sepsis-induced MOF is common in this population. Chelation therapy can be considered.

Hyperleukocytosis-Associated MOF

This leukostasis syndrome is caused by pertussis-associated leukocyte proliferating factor and is predominantly found in infant pertussis. Time-sensitive treatment appears to be leukapheresis or whole blood exchange. These therapies remove toxin and reduce pulmonary leukosequestration.

Macrophage Activation Syndrome

If inflammation remains uncontrolled in any of these MODS/MOF phenotypes, the end pathway will be the development of macrophage activation syndrome (see also Chapter 106). These patients develop hepatobiliary dysfunction and disseminated intravascular coagulation with circulating ferritin levels >500 ug/L. These patients respond well to eradication of infection/necrotic tissue, as well as IVIG, methylprednisone, plasma exchange, interferon-α, tocilizumab, and/or anakinra therapies.[20-22]

Therapeutic Approaches to SIRS/Sepsis/ALI/MOF (Table 112.2)

A patient with SIRS can be distinguished from a patient with sepsis by history. An antecedent history of surgery, pancreatitis, or trauma is supportive of SIRS. The prototype for noninfectious SIRS can be found in the spinal fusion patient or

postoperative cardiac surgery patient. Tissue injury induces the inflammatory complement/cytokine-driven response of tachycardia, tachypnea, fever, and leukocytosis. If the systemic inflammatory response worsens or occurs de novo several days after the antecedent insult, then one should consider sepsis and suspect infection. SIRS is treated by watchful waiting, fluid resuscitation if hypovolemia is suspected, and temperature control as required. Acute lung injury should be treated with supplemental oxygen as needed. SIRS is thought to be a self-limited response that can be prolonged in the presence of decreased complement production found in one-third of the population who have MBL and complement H polymorphisms. One should observe that the rate of tachycardia and tachypnea decreases with time. If sepsis is suspected, then antibiotics should be given.

TABLE 112.2

Nonspecific Therapies to Prevent and Resolve Multiple Organ Failure

1. Reverse shock in time-sensitive fashion (American College of Critical Care Medicine/Pediatric Advanced Life Support guidelines)
2. Provide effective antibiotics in time-sensitive fashion
3. Remove nidus of infection
4. Use antitoxins for toxin-mediated disease
5. Fluid removal before fluid overload >10% body weight
6. Use lung protection strategy effective tidal volume <8 mL/kg
7. Control hyperglycemia
8. Prevent drug toxicity by titrating drugs to liver/kidney function
9. Remove toxic drugs as indicated
10. Provide nutrition
11. Prevent/stop systemic hemolysis

If SIRS/sepsis progresses to organ failure or MOF, it is no longer a self-limited disease. Further support and interventions are necessary. If acute lung injury progresses, intubation and mechanical ventilation will be necessary. Intubation with ketamine as an induction agent in this setting is antiinflammatory and will not interfere with the adrenal stress response. Pulmonary capillary and epithelium leak will result in indirect ARDS, and the patient will need positive end-expiratory pressure (PEEP) to facilitate adequate oxygenation. Protective lung ventilation is recommended (see Chapters 51 and 52). Use of high lung volumes results in increased systemic inflammation and immune paralysis. For this reason, an effective tidal volume of no more than 8 mL/kg per breath is recommended. Cardiovascular management should be goal directed in a time-sensitive manner. Fluid and inotrope administration targeting capillary refill <2 seconds and normal blood pressure in the emergency department are associated with a 40% reduction in mortality.[23] Fluid, inotrope, and blood resuscitation directed to attaining superior vena cava oxygen saturation >70% reduced the incidence of MOF (renal and neurologic failure in particular) and mortality fourfold in a randomized controlled trial.[24] Administration of antibiotics and antitoxins in a time-sensitive and appropriate manner is paramount. In a retrospective cohort study involving 14 North American adult ICUs, septic patients received effective antibiotics on average 6 hours after the onset of hypotension. Administration of an effective antimicrobial within the first hour of documented hypotension was associated with a survival rate of 79.9%. However, for each subsequent hour delay in administering an effective antimicrobial average, survival decreased by 7.6%.[25] Two separate groups of pediatric ICU investigators have shown that timely administration of antibiotics prevented the development of

organ dysfunction and MODS/MOF.[26,27]

Careful attention should also be given to fluid balance. When patients become >10% total body weight fluid overloaded (eg, >1 L in a 10-kg child), the risk of mortality from MOF increases. Diuretic and/or extracorporeal therapies including intermittent renal dialysis or continuous hemofiltration should be used to remove fluid as needed after initial resuscitation, specifically to prevent fluid overload >10%. Nutrition is also important and should be given enterally if possible, but if not, then definitely through the parenteral route. Ensuring adequate glucose delivery with maintenance fluids while avoiding hyperglycemia should be a priority the first day. Enteral feedings or total parenteral nutrition can be started subsequently. Although controversy exists regarding what glucose level one should target, there is consensus that glycemic control with insulin is required at some degree of hyperglycemia. Hyperglycemia causes monocyte deactivation, increases C-reactive protein levels and inflammation, reduces immune function globally, and increases the risk of thrombosis and MOF. Insulin improves monocyte/macrophage function and reduces systemic inflammation and thrombosis.

Because cytochrome P-450 activity is decreased during SIRS/sepsis-induced MOF (~1/2 in sepsis, ~1/4 with 2 organ failures, and ~1/10 with persistent three-organ failures), adjustment of cytochrome P-450 metabolized medications is suggested when possible. Medications metabolized by the kidney should be adjusted as well according to creatinine clearance. One way to address reduced drug metabolism is to use drugs that can be followed pharmacokinetically by measured concentrations and pharmacodynamically by physiologic responses to titrated dosing. A nice rule of thumb when giving drugs that do not have pharmacokinetic or pharmacodynamic targets is to double the interval between doses for every doubling of creatinine or bilirubin depending on whether the drug is primarily metabolized through renal or hepatic pathways. Hormone synthesis can also be affected. Patients with adrenal insufficiency or thyroid insufficiency will require replacement.

Unresolving MOF should evoke suspicion that the source of infection or necrotic tissue is not being eradicated (Fig. 112.6). Persistent inflammation with thrombosis and infection is one cause of persistent MOF. Careful review of the minimum inhibitory concentration (MIC) profile of the infection should be performed, and antibiotics with the lowest possible MIC should be used. If the infection is toxin producing, clindamycin should be given to stop toxin production and IVIG administered to neutralize toxin effects. The nidus of infection may need to be removed surgically. Barie et al.[28] found that surgical sepsis mortality was 96% with failed nidus removal compared with only 4% with successful removal. Primary or acquired immune deficiency syndromes can also be the cause of uneradicated infection. Primary immunodeficiencies are usually suspected in children younger than 5 years but can present at any time in life (see also Chapter 103). Initial screening for these syndromes includes white blood cell counts, lymphocyte subsets, complement levels, gamma globulin levels, and tests for chronic granulomatous disease. Secondary immune deficiencies include severe neutropenia (ANC <500) and severe graft-versus-host disease (grade III and above) (see also Chapter 104). Neutropenia is most commonly related to bone marrow suppression induced by chemotherapy. Infection eradication and subsequent resolution of MOF occur only after restoration of the neutrophil counts. The pathobiology of graft-versus-host disease is one of donor T cells being directed against host epithelial cells (see also

Chapter 95). This results in denudation of the epithelial cell barrier with secondary bacterial and fungal infections. Treatment is difficult but is directed at stopping T cell–mediated epithelial destruction without concomitantly stopping host ability to kill infection. This is the most difficult MOF syndrome to treat.

Hemolysis is another cause of unresolving MOF. Free hemoglobin becomes a hemoglobin peroxidase when exposed to superoxide and hydrogen peroxide generated by activated white blood cells. Hemoglobin peroxidase can lead to endothelial cell injury, microvascular constriction secondary to NO scavenging, and reduction in macrophage viability.[29] The prototype of this form of MOF is found in children with sepsis who are on poorly functioning extracorporeal membrane oxygenation (ECMO) support. If the ECMO circuit induces excessive hemolysis (free hemoglobin >10 ug/L), MOF can ensue. The approach should be to attempt to stop ongoing hemolysis by changing oxygenator circuits, adding a second venous cannula, and reducing ECMO flow (see also Chapter 59). In hemolytic disease such as sickle cell anemia, plasma exchange can help reduce hemolysis and resolve MOF.

Rare medication toxicities can also contribute to unresolving MOF. Patients with intrathecal baclofen pump infusions can develop baclofen withdrawal infusion syndrome when infusions are stopped. Linezolid toxicity can also progress to overwhelming lactic acidosis and MOF. Linezolid's antimicrobial activity is mediated through bacterial ribosome poisoning. Unfortunately, human mitochondria can similarly be poisoned by linezolid. Baseline lactate levels should be obtained, and if lactate levels increase while on linezolid, the drug should be stopped before lactic acidosis ensues. Nitroprusside at high/prolonged dosing can induce cyanide poisoning. Cyanide and isocyanate levels should be followed when giving this medication. Propofol can cause propofol infusion syndrome associated with overwhelming lactic acidosis. Propofol should not be used for long-term sedation in children <3 years of age. Systemic drug reactions including Stevens-Johnson syndrome and delayed hypersensitivity syndromes must also be considered. These scenarios call for discontinuation of the offending agent and then watchful supportive care. This can sometimes be tricky. For example, the delayed hypersensitivity skin rash may be difficult to discern in children with greater pigmentation. For patients with sulfa drug–related Stevens-Johnson syndrome, it is important to realize that furosemide is also a sulfonylurea.

Even in clinical settings without sophisticated research tests, patients with persistent MOF can be phenotyped. New-onset thrombocytopenia with MOF, increase LDH, ± schistocytes, and renal dysfunction likely reflects a thrombotic microangiopathy that resides within the disseminated intravascular coagulation –thrombotic thrombocytopenic purpura continuum. This complex coagulopathy can be treated with plasma infusion/plasma exchange, protein C, antithrombin III, pentoxifylline, prostacyclin, and/or heparin. New or persistent bacterial or fungal infections in a patient with MOF who does not have evidence of primary/secondary immune deficiency nor an uneradicated nidus of infection are highly suggestive of immune paralysis/lymphoid depletion syndrome. Immune-suppressant therapies should be rapidly tapered in these patients. Dexamethasone in particular should be stopped and transitioned to hydrocortisone. GM-CSF can be given subcutaneously at 125 ug/m^2 daily subcutaneously to reverse immune paralysis. If IgG levels are <500 ug/L, IVIG should be considered. If the CD4 count is low, antifungal/antiviral/antiprotozoal prophylaxis can be considered. Patients with

sequential MOF that begins with ARDS and progresses to hepatorenal syndrome should be recognized and treated accordingly. If the child has EBV-related posttransplant lymphoproliferative disease (high EBV titers), rapid immune suppression tapering is recommended along with rituximab and IVIG therapy. If a previously healthy infant has pneumonia and a white blood cell count >27,000/uL, the diagnosis of pertussis-related hyperleukocytosis should be aggressively pursued. Investigators in the United Kingdom provide a useful algorithm to direct use of leukoreduction therapies in this population.[30] A ferritin level should be investigated in patients who develop hepatobiliary dysfunction and disseminated intravascular coagulation. If ferritin is >500 ug/L, the diagnosis of macrophage activation syndrome should be considered. Its treatments include IVIG, methylprednisone (not dexamethasone), plasma exchange, anakinra, and tocilizumab. A history of chronic transfusions, a ferritin >1000 ug/L, and an iron-binding capacity <50% suggest secondary hemochromatosis instead. These patients commonly have pancreatic dysfunction. They should be treated with iron chelation therapy; however, because these patients are prone to aspergillus infection during chelation therapy, appropriate antifungal coverage is recommended.

Time Course of SIRS/Sepsis-Induced MODS/MOF

In general terms, SIRS/sepsis should resolve within 5 days. MODS/MOF resolves over 1 week to 3 months. MOD and MOF are related to epithelial cell and endothelial cell dysfunction/damage/apoptosis. If significant hypoxia/ischemia is the causal event, MOF will not resolve until (1) reepithelialization of lung, liver, and kidney occurs; (2) reendothelialization of organs occurs; and (3) canalization of microvessels occurs. These processes take 6 weeks to 3 months. Accordingly, health care providers should be patient and not give up on MOF-afflicted children too early!

Summary

Inflammation and immunity are the basis of SIRS/sepsis-induced MODS/MOF. SIRS and sepsis occur more commonly in patients with reduced MBL complement and inhibitory complement function. MODS/MOF occurs in patients who have epithelial/endothelial cell injury and/or microvascular thrombosis caused by underresuscitated shock, ischemia-reperfusion, unresolved inflammation, unresolved infection, and/or drug/toxin-induced mitochondrial injury. SIRS/sepsis is managed with fluids, temperature control, and antibiotics if infection is present, and it usually resolves within 5 days. This approach prevents the development MOF/MODS. If treatment is delayed, MODS/MOF can occur. Treatment is then used to reverse shock, remove infection, resolve inflammation, and reverse microvascular thrombosis. Personalized phenotype-specific therapies are directed to recovery of endothelial, epithelial, mitochondrial, and immune function. Survival can be 90% with a patient approach.

SECTION X

Environmental Hazards

OUTLINE

CHAPTER 113

Bites and Stings

Alfredo Maldonado, Nagela Sainte-Thomas, Erika Vazquez

PEARLS

- Snakebite-related injury and death are reduced most effectively by rapid transport, intensive care support, and the administration of antivenin.
- Measures not recommended for snakebite first aid are incision, suction, tourniquets, electric shock, ice directly on wound, alcohol, or folk therapies.
- Antivenins can induce immediate anaphylactic (type I hypersensitivity) or anaphylactoid reactions, which can be rapidly life-threatening. Airway swelling, wheezing, shock, and urticaria characterize these reactions. Anaphylactic and anaphylactoid reactions are treated with antihistamines, histamine (H_2) blockers, epinephrine, steroids, and ventilatory/circulatory support as needed.
- All children with snake envenomations should be admitted to the hospital. Serious effects can be delayed and can recur even after treatment with antivenin.
- Typically, a widow spider bite site has a "target" appearance. There may be a central reddened, indurated area around the fang puncture site(s) surrounded by an area of blanching and an outer halo of redness. The findings around the bite wound may be subtle.
- Bees, wasps, and ants can cause toxic, even fatal, complications when they attack en masse. Sting removal after a honeybee sting should be done as quickly as possible, regardless of the method of removal.

The general principles of envenomation medicine are similar around the world, although the availability of resources varies widely. A comprehensive discussion of all available antivenins is beyond the scope of this text.[1] In consideration of space constraints, the scope of this textbook, and its audience, this chapter focuses on US antivenins. Readers are encouraged to become familiar with the prescribing information for the antivenin(s) available in their area(s) of practice for the envenomations they may encounter.

Snakebites

Snakebite is a particularly challenging clinical problem because of the wide variety

of toxic effects. Children with snakebites may have little more than a fang puncture mark, or they may have multisystem failure and death.[2,3] Part of this is due to the extreme variability of snake venom, even within the same species.[4] Snake venom contains multiple enzymes, proteins, and peptides that can damage local tissues and have serious systemic effects. Unfortunately, it is difficult to predict at the time of the bite which patients will have relatively mild symptoms and which will have a rapidly progressive and potentially fatal envenomation syndrome.

Snakebite envenomation syndromes can be loosely associated with snake family. Viperidae includes old-world vipers and pit vipers (collectively referred to as viperids). Most snakebites in the United States are inflicted by pit vipers, which include rattlesnakes, cottonmouths (also known as water moccasins), and copperheads.[5] All pit vipers have a triangular head, elliptical pupils, and a heat-sensing pit between the eye and nostril (Fig. 113.1).[6] The pit organ has thermal receptors that can detect temperature differences of 68°C at 1.5 m in predatory interactions and 108°C at 1 m in defensive contexts (A. Krochman, personal communication, January 17, 2005). The family Elapidae (“elapids”) includes cobras, coral snakes, kraits, and mambas.[7] Their venom effects can be as diverse as the species that make up this family of snakes. Cobras are hooded, high-profile snakes that inhabit Africa and southern Asia (Fig. 113.2). The coral snakes of the Americas and kraits of Asia and India are often small, shy, colorfully banded snakes (Fig. 113.3). Mambas in Africa are long, lean, and fast. Australian elapids can be large and nondescript. Sea snakes possess some of the world's most toxic snake venom, although few bites occur mostly because of the marine distribution and nonaggressive temperament of these snakes. Most snakes from the Colubridae family (“colubrids”) are considered harmless, although several species possess venom and some have primitively specialized teeth to facilitate venom delivery. Some, such as the boomslang in Africa, are considered dangerous to humans, and antivenin is produced.

Epidemiology

It is estimated that approximately 1,841,000 envenomations and 94,000 deaths occur worldwide annually from snakebites.[8] It is often stated that children are more severely affected by snakebites than adults.[9] Indeed, some preliminary data suggest that smaller patients have increased severity. In terms of evidence, however, there is little to support the assertion that outcomes for children are worse than adults. For example, of more than 100,000 exposures and 24 deaths described by the American Association of Poison Control Centers (AAPCC) since its first report in 1983, only a relatively small percentage of the deaths are described in pediatric patients.[10] In some respects, children are no different from adults when it comes to snakebite. For

instance, antivenin dosing is not based on the patient's weight,[11,12] yet there are a few concerns specific to pediatric patients. Because young children may not be able to give a good description of the snake or circumstances, it may be unclear whether a venomous snake has bitten them.

Pathophysiology

Although viper and pit viper venom composition varies from snake to snake, components can lead to capillary leak, abnormal clotting, inefficient muscle movement, or neurotoxicity. Capillary leak and abnormal clotting can lead to tachycardia, hypotension, or even hemorrhagic shock. Neurotoxicity or inefficient muscle movement can lead to respiratory difficulty or distress.[13] Meanwhile, proteolytic enzymes, predominant in viper and pit viper venoms, digest tissue. The longer that enzymatic components of venom have time to work, the more tissue gets damaged. Thus “time is tissue.”[14] The sooner that antivenin can be started, the sooner that irreversible injury can be prevented.[15] After tissue is injured by way of digestion, however, antivenin will not reverse the damage; it will have to heal over time.[16] Myotoxicity and rhabdomyolysis can ensue.

Envenomation by most elapids is notable for severe neurologic dysfunction, such as cranial nerve abnormalities, paralysis, and respiratory arrest. Some elapids, however, such as spitting and monocellate cobras, can also cause local necrosis. Most do not induce coagulopathy. Other symptoms and signs may include swelling, lethargy, vomiting, chest pain, and shock. Some cobras and cobralike species can “spit” venom toward the face of an antagonist, which can result in eye pain and visual impairment. Sea snake envenomation can cause profound neurotoxicity and myotoxicity but generally does not induce coagulopathy or result in serious local injury. Sea snakes are found in waters around Southeast Asia and Australia. Additionally, some individuals may experience anaphylactic or anaphylactoid reactions to venom.[17,18] Finally, some responses can be attributed to anxiety, although this should be a diagnosis of exclusion.[6]

Clinical Presentation

Immediately after a snakebite, the only apparent manifestation may be fang puncture wounds. If a patient is seen soon after a snakebite, an envenomation syndrome might not have developed yet. The onset of symptoms and signs can occur rapidly, or it may be insidious. Most cases of envenomations can be identified within 6 hours of the bite.[19] Generally, the more severe an envenomation, the more rapidly it progresses; however, even a slowly progressing envenomation can lead to severe sequelae. If a patient is seen very late, the envenomation could have already run its course, and antivenin will not be as effective.[15]

Snakebites by pit vipers and vipers cause pain around the bite site as tissues distort with swelling. There may or may not be associated taste changes. Difficulty breathing can follow many types of venomous snakebites and can progress to respiratory distress or failure in some cases. Patients may experience nausea, vomiting, or diarrhea, and venom-induced coagulopathies (often associated with viper and pit viper envenomation) can lead to hematemesis, hematochezia, or both. Certain snakebites, such as those inflicted by most elapids and some populations of

rattlesnakes, can also be associated with neurologic symptoms, such as motor weakness or paresthesias. Syncope or lethargy can result from severe or prolonged hypotension.[6] Vital signs may reflect tachycardia, hypotension or hypertension, tachypnea, or hypoventilation. On physical examination, there may be one, two, or more fang puncture wounds, or none may be discernible. There is usually tenderness and swelling surrounding the bite site, which expands as the venom spreads locally. Other local signs can include erythema, ecchymosis, and bullae after viperid envenomation (Fig. 113.4). Systemic evidence of viperid envenomation may manifest in many ways. There may be abnormal bleeding, such as prolonged bleeding from fang puncture wounds or IV cannulation sites. Patients may have epistaxis or gingival bleeding. Serious and potentially life-threatening bleeding may manifest via the gastrointestinal tract or intracranially. In extremely rare instances, snakebite can also cause hypercoagulability, which can lead to infarction. Additionally, there may be neurologic signs, such as ptosis (Fig. 113.5), and muscle fasciculations, or "myokymia."[6]

Diagnostic Studies

Initial laboratory tests after pit viper or viper envenomation should include a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), fibrinogen, and a type and screen. Venom-induced coagulopathy is common after many types of viperid envenomations and is most typically characterized by thrombocytopenia and hypofibrinogenemia. Even if coagulation values are normal on presentation, they may need to be rechecked depending on the clinical scenario. Venom-induced coagulopathies can develop late, recur, or persist. If initial laboratory findings are abnormal, more frequent monitoring may be necessary depending on how severely abnormal they are and how they respond to treatment. If the findings are abnormal, repeating the CBC, PT, PTT, INR, and fibrinogen tests 1 hour after completion of an infusion of antivenin may be helpful to monitor treatment efficacy. When laboratory values are rechecked, in addition to the initial laboratory panel, additional blood should be sent for creatine kinase (CK), electrolytes, blood urea nitrogen, and creatinine clearance. All snakebites can result in rhabdomyolysis, which usually responds to aggressive fluid hydration, but can require dialysis if myoglobinuric renal failure develops. In certain regions, such as Australia, venom detection kits (eg, enzyme-linked immunosorbent assays) may be available to help identify species and guide specific antivenin selection. Other diagnostic studies may be indicated on the basis of a patient's medical history or special circumstances.[6]

Pitfalls

It is possible that a snakebite might be mistaken for a puncture wound from another cause (eg, from a plant thorn), if the patient is seen very early, if the envenomation is mild, or if there are difficulties obtaining a reliable history. If there is any question about whether a patient has been bitten by a venomous snake, an observation period and diagnostic studies may help clarify the diagnosis. Snakebites usually progress if significant envenomation has occurred. Certain signs (eg, ecchymosis), symptoms (eg, local paresthesias), and laboratory data (eg, thrombocytopenia, hypofibrinogenemia), if affected, are fairly consistent with viperid envenomation. If a bite by an elapid is suspected, envenomation should be assumed until proven otherwise after adequate observation and evaluation. Evaluation may include the Tensilon test in those patients presenting with a myasthenia-like syndrome.[20]

Prehospital Care

The factors that most reduce snakebite-related injury and death in the United States are rapid transport, intensive care, and administration of antivenin.[21] All patients with snakebites should be transported to the hospital as expeditiously and safely as possible, preferably through a 911 call (where available). The following measures are not recommended for first aid: incision, suction, tourniquets, electric shock, ice directly on wound, alcohol, or folk therapies.[22-24] Insufficient evidence exists for splinting or positioning (eg, above or below the level of the heart). Patients with bites, especially in the lower extremities, should not walk as it may increase local

venom absorption. Therefore the extremity should initially be maintained in a neutral position of comfort. The Australian technique of pressure immobilization resulted in significantly longer survival but higher intracompartmental pressures after artificial, IM western diamondback rattlesnake envenomation in a pig model.[25] This technique involves immediately wrapping the entire extremity that was bitten starting at the bite site and proceeding proximally with an elastic Ace wrap or crepe bandage as tightly as one would wrap for a sprain and then splinting and immobilizing the extremity. Although pressure immobilization is not recommended widely, certain scenarios may warrant its use. It is generally not recommended for most viper bites or for bites by spitting cobras, but it is recommended for most types of Australian fauna, cape cobras, kraits, coral snakes, mambas, and sea snakes. Once pressure immobilization is placed, it should not be removed until preparations are made to manage acute toxicity and/or immediate hypersensitivity because of a potential bolus effect after its removal. Although it is difficult to predict snakebite severity at the time of the bite, certain factors may reflect increased likelihood of a more severe envenomation: large snake size, dangerous snake species, small patient size, prolonged fang contact, previous snakebites (treated or not) or exposures to snakes, or delays to medical care.

Emergency and Critical Care

All emergency personnel should be able to distinguish a venomous from a nonvenomous snake if it occurs naturally in their region of practice. If there is uncertainty about whether a particular snake is venomous, consider taking photographs of the snake from a safe distance of at least 6 feet away using a digital or Polaroid camera. These images can be seen immediately and may help make clinical decisions. Although it may be helpful to identify the species of snake,[16,26] transporting it (alive or dead) is discouraged because of inherent dangers with capturing it. On scene, snakes should only be moved or contained if absolutely necessary. A snake hook or long shovel may be helpful to move the snake into a large, empty trash canister, where it can be recovered by professionals, such as an animal control agent.

Airway support, advanced pediatric life support protocol, or both should be provided as needed. Respiratory insufficiency or failure may require endotracheal intubation and mechanical ventilation. The administration of atropine is suggested in patients with mamba envenomation due to its anticholinesterase activity causing hypersalivation.[27] Vital signs should be monitored frequently, supplemental oxygen provided, and ongoing monitoring instituted (cardiac, blood pressure, and pulse oximetry). Two peripheral IV cannulae should be started. Central venous or intraosseous access may need to be obtained. It may be appropriate to avoid placing a central line in a noncompressible site (eg, internal jugular) after viperid envenomation because of the risk of bleeding from venom-induced coagulopathy. A normal saline fluid bolus of 20 mL/kg should be administered. If there is evidence of shock, a second fluid bolus should be administered and ongoing resuscitation instituted according to Pediatric Advanced Life Support guidelines. Because viperid envenomation can induce coagulopathy and bleeding, transfusion may be required after treatment with two fluid boluses. Packed red blood cells (10 mL/kg) should be administered for acute, life-threatening blood loss or anemia. Persistent hypotension

may require the administration of vasopressors and inotropic agents. Urine output may be used as a measure of adequate hydration and to check for the occurrence of rhabdomyolysis. The patient should take nothing by mouth until it has been determined that the patient will not need airway control and mechanical ventilation.

After pit viper or viper envenomation, remove rings, other constricting jewelry, and clothing in anticipation of severe swelling. The expanding area of swelling and tenderness can be used to follow the progression of viperid envenomations. Tenderness is more sensitive than swelling for detecting progression. Also, it is preferable to follow the advancing edge of tenderness or swelling than to follow serial measurements of circumference. Palpate until the edge of advancing tenderness is found. Mark this leading edge with a permanent marker and write the time alongside. Repeat this often enough to gauge progression. This may require checking the site every 15 to 20 minutes initially. Once antivenin is started, it should still be followed every 1 to 2 hours.

All hospitals should stock at least enough antivenin to treat one patient. This should be arranged ahead of time if possible, although sometimes there are antivenin shortages and other resource challenges. Presently only one agent is commercially available in the United States for treatment of pit viper envenomation: Crotalidae Polyvalent Immune Fab (Ovine), which goes by the trade name CroFab (Protherics Inc., Nashville, Tenn.).[28] Antivenin Crotalidae Polyvalent is no longer produced. Several manufacturers produce antivenin for bites in Africa (eg, South African Vaccine Producers), Asia, Europe, and Australia (eg, Commonwealth Serum Laboratories [CSL]), and the Americas (eg, Instituto Bioclon in Mexico, Instituto Clodomiro Picado in Costa Rica, and the Butantan Institute in Brazil). A polyvalent sea snake antivenin (CSL) is the drug of choice for sea snake envenomation, but tiger snake antivenin may have adequate efficacy if sea snake antivenin is not available. Information on antivenin should be researched ahead of time, and practitioners should be familiar with sources and administration techniques for the antivenins available for envenomations they may encounter. Each antivenin has varying specificity, efficacy, and safety. Some antivenins developed for one species may have some efficacy against other closely related species. If an exotic envenomation is encountered in the United States, calling the AAPCC or consulting the Antivenom Index may help locate antivenin. Many zoos stock antivenins for the exotic species they keep. If antivenin is unavailable, a patient with an elapid or sea snake envenomation may need his or her airway secured and ventilatory support provided for days or even weeks. Meanwhile, hypotension should be treated with IV fluids and then vasopressors. Edrophonium may temporarily improve weakened muscles of respiration after elapid envenomation while awaiting antivenin.

Various suggested methods determine the need for antivenin. Many grading scales are available, but it is better to treat a patient on the basis of envenomation progression or potential. Grading scales should not be used for elapid or sea snake envenomations. Antivenin should be given promptly for best results, although it may have benefit for days to weeks after an envenomation. Any time antivenin is given, allergic reactions should be anticipated. It may be helpful to know whether the patient has allergies or previous exposures to papain, papaya or animal serums, or other agents used to make antivenin. Pediatric dosing of antivenin is the same as adult dosing and is dependent on snake species and the patient's symptoms.[29] Obtain informed consent when possible. Many of the principles of antivenin

administration are similar. The technique for administering CroFab is outlined as an example. A starting dose of CroFab is 4 to 6 vials and increases to 8 to 12 vials in patients who present with immediate life-threatening venom effects, such as shock or serious active bleeding.[30,31] Each vial should be mixed with 18 mL of 0.9% saline with inversion. This reduces overall dissolution time to 3 minutes from the previous practice of 10 to 30 minutes when using 10 mL of sterile water.[32] It is best to swirl or roll the vials between the hands rather than shake them. After each vial goes into solution, it should be further diluted into a total volume of 250 mL of normal saline. No skin test is recommended for CroFab, although manufacturers of many other types of antivenins recommend skin testing. With CroFab, the infusion is started slowly, at a rate of 1 mL/min for the first 10 minutes. While the infusion is started, a physician skilled in resuscitation should be at the bedside. Difficult airway equipment, epinephrine, diphenhydramine, and a histamine (H_2) blocker (eg, cimetidine) should be immediately available. If the infusion is tolerated for the first 10 minutes without evidence of an adverse reaction, the rate should be increased to complete the total volume of 250 mL/hour. If there is a problem at any time, stop the infusion, treat the adverse reaction accordingly, and reassess the need to continue antivenin treatment. A physician should be nearby at all times during the remainder of the infusions. Repeat four- to six-vial increments until initial control is achieved. Initial control is defined as the arrest or significant slowing of progression of any and all components of the envenomation syndrome (ie, minimal to no further advancement of swelling, improvement of systemic effects, and improving coagulopathy). Assess at up to 1 hour after each dose. After initial control is achieved, a maintenance dose of two vials of CroFab every 6 hours for three doses is recommended in the prescribing information, although maintenance dosing has been shown not to reduce recurrence phenomena.[33] Read the package insert for additional details.[30] For pharmacokinetic reasons that are not entirely understood, recurrence phenomena are associated with antivenins.[34-36] Local recurrence is the return of new progressive swelling after initial control. That is, the leading edge of tenderness or swelling begins to advance again. An additional two vials of CroFab should be given as soon as progressive swelling recurs, and more antivenin may be necessary to regain control, although experience has shown that local effects may continue to progress despite additional antivenin. Patients with rattlesnake bites commonly have thrombocytopenia and hypofibrinogenemia, which can resolve with CroFab and then recur (coagulopathy recurrence). Indications for an additional two vials of CroFab are serious abnormal bleeding, fibrinogen less than 50 μg/mL, platelet count less than 25,000 mm^3, INR greater than 3, multicomponent coagulopathy, worsening trend in patient with prior severe coagulopathy, high-risk behavior for trauma, or comorbid conditions that increase bleeding risk. Coagulopathy can recur as late as 2 weeks or more after treatment.

Blood products may be necessary if antivenin does not correct the coagulopathy or if there is an imminent risk of serious bleeding. Transfusion of the appropriate blood product is generally recommended for life-threatening bleeding, platelet count less than 20,000/mm^3 and refractory to antivenin, or hemoglobin less than 7 g/dL. Consider CT of the brain if the patient has a severe headache or an altered level of consciousness with a severe coagulopathy. Ocular exposure to venom necessitates prompt and copious irrigation and an ophthalmology evaluation.

Pain relief can be provided by incremental doses of either fentanyl or morphine,

titrated to clinical effect. Nonsteroidal antiinflammatory drugs (NSAIDs) are contraindicated for approximately 2 weeks after viper and pit viper envenomation because they can contribute to venom-induced coagulopathy and bleeding.

Prophylactic antibiotics are unnecessary. Empiric antibiotic therapy should only be started if an infection develops and once aerobic and anaerobic wound cultures have been obtained. If an abscess occurs, it should be drained in standard fashion. An infected snakebite should prompt a further examination of the wounds for potential retained teeth or fangs.[5]

Envenomations by vipers and pit vipers are remarkable for the amount of swelling they can produce. With prompt and adequate antivenin treatment, fasciotomy or digit dermotomy is rarely indicated, even after severe viperid envenomation.[37-40] Fasciotomy, however, may be indicated if measured compartment pressures remain persistently and severely elevated despite adequate antivenin. Antivenin has been shown to limit the decrease in perfusion pressure associated with compartment syndrome.[41] Compartment syndrome may manifest subjectively, with complaints of increasing pain, and objectively, with tenderness on passive muscle stretch, a rock hard feel to the compartment, or a diminished capillary refill. True compartment syndrome, however, is rare after snakebites, even in patients with severe swelling. It may be difficult to distinguish compartment syndrome from the effects of envenomation. Similar to compartment syndrome, viperid envenomation may cause a bluish discoloration of the skin or pallor (because of subcutaneous bruising), severe swelling, paresthesias, and pain. If effects are only caused by envenomation and the patient does not have compartment syndrome, capillary refill should be normal and compartmental pressures should not be elevated. If compartment pressures are elevated, Gold et al.[38] recommend limb elevation, along with IV mannitol (1 to 2 mg/kg) administration and an additional four to six vials of CroFab over 1 hour. Consultation with a surgeon (eg, general, orthopedic, or hand) should be initiated concurrently. Compartment pressures should be measured before surgical intervention.

Therapeutic Complications

Antivenins can induce immediate anaphylactic (type I hypersensitivity) or anaphylactoid reactions, which can be rapidly life-threatening. Airway swelling, wheezing, shock, and urticaria characterize these reactions. Anaphylactic and anaphylactoid reactions are treated with antihistamines, H_2 blockers, epinephrine, steroids, and ventilatory/circulatory support as needed.

Antivenins can also cause serum sickness, a delayed (type III hypersensitivity) reaction characterized by fever, urticaria, lymphadenopathy, and polyarthralgias days to weeks after treatment. Although serum sickness can be an uncomfortable experience, it is usually benign and self-limited, and the patient is treated on an outpatient basis with antihistamines and steroids. Also, adverse reactions are much less common after treatment with Fab-based antivenins than they are with whole immunoglobulin formulations.[15] All commercially available antivenins in the United States use mercury, in the form of thimerosal, as a preservative, which in high doses can cause nerve and kidney toxicities in small children.[30]

Resources

The AAPCC can assist in the management of envenomations. Poison control may be contacted at 800-222-1222.

Disposition

It is prudent to admit all children with snake envenomations to the hospital. Serious effects can be delayed and can recur even after treatment with antivenin. Therefore close observation with monitoring, frequent measurements of swelling/tenderness, and neurologic checks for at least 24 hours are recommended. This degree of monitoring may require transfer and admission to a pediatric intensive care unit (PICU). On discharge, the patient should return immediately for further swelling or severe pain. Additionally, the patient should return immediately for any abnormal bleeding or bruising, dark tarry stools, petechiae, or severe headache. Also, patients should be given wound care instructions and told to return for signs of wound infection. Signs of serum sickness should be outlined, and the patient should return or follow up if these signs show up any time in the few weeks after treatment with antivenin. The patient should be told not to take NSAIDs for 2 weeks after a pit viper or viper bite. Instead, acetaminophen with or without a combined opiate analgesic should be prescribed. The patient should not engage in contact sports or schedule any elective surgery or dental work for 2 weeks after viperid bites. Recommend that the patient drink plenty of liquids, and advise that the patient return if decreased urination or cola-colored urine is noticed. Some patients may need referral to a physical therapist. Blisters, blebs, and bullae should be left in place but may need debridement along with necrotic tissue after several days, so surgical referral as appropriate is suggested.[37] Skin grafting is sometimes necessary. If the patient was bitten on the foot or leg, crutches and crutch training should be provided. The patient should be encouraged, however, to bear weight and mobilize the extremity as tolerated. In some cases, a next-day wound check may be appropriate. Otherwise, the patient should return or follow up in a few days.[35] At that time, laboratory tests may need to be repeated, depending on the clinical scenario. Retreat with antivenin as needed.

Prognosis

Most patients recover fully after snakebite. Viperid envenomation results, however, in tissue loss, deformity, or loss of function in a clinically significant percentage of patients.[9,42]

Preventative measures should be explained to parents and children. Teach children to leave snakes alone. They should never touch, handle, or try to kill venomous snakes. Many people are bitten when they are intentionally interacting with the snake. Even after a snake is believed to be dead, fangs still can inject venom. Snakes that were presumed dead have bitten many people and delivered serious, even fatal, envenomations. Additionally, a snake can strike faster and farther than one might think—about half its body length. Children should stay at least two “giant steps” away from snakes. If a child finds a snake, he or she should tell an adult. Additionally, tell children not to reach or step into places that they cannot see. Wearing boots and jeans may prevent some (but not all) snakebites.

Future Directions

Modifications of the antivenin molecule or formulations may reduce recurrence phenomena, and this is being investigated. Several antivenins are being developed by Instituto Bioclon for use in the United States and other parts of the world.

Widow Spider Bites

Widow spiders belong to the genus *Latrodectus* and are represented in the United States by the black widow (Fig. 113.6), brown widow, and red-legged widow.[43] There are approximately 30 species of widow spiders worldwide.[44] The redback spider is endemic to Australia. Other species, such as the kara kurt and black button spider, are found in other parts of the world, including Europe, South America, and South Africa. The adult female black widow spider is approximately 2 cm in length and shiny black with a red-orange hourglass or spot on the ventral abdomen. The male is much smaller, brown, and much less commonly implicated in human envenoming. Juvenile females are also brown with yellow and white markings but have the general body shape of the adult. Males and juveniles have a pale hourglass shape, similar to adult females. Webs are irregular; low lying; and commonly seen in garages, barns, outhouses, and foliage. Other widow spiders around the world are generally black but may have red spots, such as the kara kurt, or a dorsal red stripe, such as the redback spider. The brown widow is brown with red and yellow markings. Similar species include the false black widow or cupboard spider, *Steatoda* spp., which can produce symptoms that are similar in character but milder in intensity than widow spiders.

FIG. 113.6 Black widow spider *(Latrodectus hesperus).* (Photo courtesy Sean Bush, M.D.)

Epidemiology

No deaths caused by widow spider envenomation have been reported to the AAPCC since its first annual report in 1983. A few recent deaths have been reported, however, after a black widow spider bite in Greece, Mexico, and the United States.[45-47] From 2000 to 2008 a total of 23,409 *Latrodectus* spp. exposures were reported in 47 states, with exposures peaking in September.[48] In peridomestic areas, widow spiders are found in dark or dry places—areas of clutter, woodpiles, underneath outdoor furniture, etc. In natural environments, widow spiders live under stones or logs, in shrubs, or in small mammal burrows.[44]

Pathophysiology

The envenomation syndrome, known as *latrodectism,* caused by the various species of widow spiders around the world is similar.[49-51] The predominant clinical effects after widow spider envenomation are neurologic and autonomic.

Clinical Presentation

Typically, the bite site has a “target” appearance. There may be a central reddened, indurated area around fang puncture site(s) surrounded by an area of blanching and an outer halo of redness (Fig. 113.7). The findings around the bite wound may be subtle, and the wound does not become necrotic. Puncture wounds may not be seen due to the spider's small fang size.[44] The predominant symptoms frequently involve painful muscle cramping. If a person is bitten on the lower extremity, pain usually progresses from the foot, up the leg, and into the back and abdomen. If a person is bitten on the upper extremity, pain usually progresses from the hand, up the arm, and into the chest and abdomen. Abdominal pain may be so severe as to mimic an acute abdomen, with tenderness and rigidity.[52] Diaphoresis locally around the bite site is distinctive for widow spider envenomation, although diaphoresis may be diffuse and profuse or it may manifest in unusual patterns remote from the bite site. Local piloerection is sometimes seen. Patients may exhibit “*Latrodectus* facies” (Fig. 113.8), which is characterized by spasm of facial muscles, edematous eyelids, and lacrimation, which may be mistaken for an allergic reaction. Other common symptoms and signs include high blood pressure, rapid heart rate, nausea, vomiting, headache, and anxiety. In a typical progression, symptoms begin within an hour, reach maximum intensity by about 12 hours, and can last for days to weeks. Unusual presentations have been described after widow spider envenomation including pulmonary edema, myocarditis, cardiomyopathy, and priapism.[45,53-55] It has been suggested that there may be increased danger to pediatric patients with widow spider bites and that this population may require more aggressive treatment and hospitalization, although this assertion has been challenged.[56] Little evidence supports either assertion. A recent and well-documented fatality from widow spider envenomation involved a healthy 19-year-old woman. Other recent reports involved adults as well.

Diagnostic Studies

Rhabdomyolysis has been reported after widow spider envenomation,[53] so a total CK test should be performed if severe envenomation develops. If the patient has respiratory difficulty, a chest radiograph should be obtained. Electrocardiography or echocardiography may detect that rare case of venom-induced myocarditis in a critically ill patient. Otherwise, diagnostic tests are not particularly helpful. If the diagnosis is uncertain, evaluation should be aimed at uncovering other causes such as appendicitis.

Pitfalls

Misdiagnosing an acute abdomen in a patient with a widow spider envenomation could lead to unnecessary surgery.

Emergency and Critical Care

Two basic treatment options are available. Widow spider envenomation can be

managed with antivenin or a combination of pain medications and sedatives. Risks and benefits are associated with each. Management with an opioid analgesic, such as fentanyl 1 μg/kg/dose IV/IM, may repeat at 30- to 60-minute intervals or morphine in increments of 0.02 mg/kg up to 0.1 to 0.2 mg/kg IV/IM, and a benzodiazepine such as lorazepam 0.01 to 0.03 mg/kg IV is generally considered safe. This treatment option, however, is purely palliative, and symptoms may persist for days or even weeks. The pain and discomfort associated with widow spider envenomation can be severe. In contrast, antivenin is remarkably effective and can completely ameliorate the symptoms within 30 minutes.[51] Unfortunately, it can be associated with severe side effects and death.[57] Because death is so rare after widow spider envenomation, some would argue that the treatment is more dangerous than the bite itself. Historically, IV calcium was recommended, although it has now been found to be ineffective.[57] Several antivenins have been manufactured including Black Widow Spider Antivenin (equine) in the United States, Australia Redback Spider Antivenom, and South Africa spider antivenin (button spider).[1] Indications for antivenin use and routes of administration vary around the world. According to the package insert of Black Widow Spider Antivenin, one vial should be reconstituted in 2.5 mL of the sterile diluent supplied. It is further diluted into a volume of 50 mL saline and administered IV over 15 minutes. Patients usually experience dramatic relief within an hour of treatment with one vial, although sometimes two and rarely three vials are necessary. It may be effective days, weeks, or possibly even longer after the envenomation.[58] The risk of allergy to antivenin must be weighed against the benefit of relieving prolonged discomfort, avoiding hospitalization, and preventing complications. Although most widow spider envenomations can be managed with opioid analgesics and benzodiazepines, antivenin may be indicated for patients who have severe envenomations with pain refractory to these measures. It is prudent to have medications used to treat anaphylaxis at bedside during administration of the antivenin. Antivenin should be given if there is an imminent risk of a severe complication of envenomation. Factors that could increase the risk of antivenin include allergy or previous exposure to horse serum or a medical history of reactive airways.[59] Antibiotics are not indicated for widow spider envenomation. Also, update tetanus prophylaxis as appropriate.

Therapeutic Complications

Serious, even fatal, adverse reactions have been documented after treatment with black widow spider antivenin. Anaphylactic and anaphylactoid reactions to antivenin can occur and may be even more life-threatening than the envenomation itself. Skin testing, with the intradermal injection of 0.02 mL of the test material supplied and the observation for an urticarial wheal in 10 minutes, variably predicts immediate hypersensitivity to antivenin and may influence the decision regarding its administration. Premedication with antihistamines (H_1 and H_2 blockers) may reduce the likelihood that an acute allergic reaction will occur. Serum sickness, characterized by fever, urticaria, lymphadenopathy, and polyarthralgias, can occur days to weeks after treatment and is treated with antihistamines and steroids.

Resources

The AAPCC may be helpful with management of widow spider envenomations and can be contacted at (800) 222-1222.

Disposition

Because it so effectively resolves symptoms, antivenin has been shown to decrease the need for hospitalization after widow spider envenomation. Admission to the hospital and possibly the PICU is prudent for severely symptomatic children, those with intractable pain and contraindications to antivenin, those with unusual complications of envenomation, and those who have anaphylaxis to antivenin. Patients who experience relief with opioid analgesics, benzodiazepines, or antivenin may be discharged. On discharge, signs of serum sickness should be outlined, and the patient should return or follow up if these signs show up any time in the few weeks after treatment with antivenin.

Prognosis

The envenomation syndrome usually resolves completely, with or without treatment, and does not leave the patient with long-term sequelae. Death is rare.

Prevention

Spider bites may be prevented by eliminating the spider's food and habitat; by shaking sheets, shoes, and clothing before donning; by keeping the child's bed away from the wall; and by brushing spiders off rather than crushing them.

Future Directions

Safer antivenins are being developed and investigated, including an antivenom consisting of highly purified equine F(ab)2 fragments.[60]

Hymenoptera Stings (Bees, Wasps, and Ants)

Stings by bees, wasps, and ants are less of a toxicologic concern than they are an allergic one. Details on treatment of anaphylaxis are covered elsewhere in this text. The focus of this section will be mass envenomation. Any bees, wasps, or ants can cause toxic, even fatal, complications when they attack in large numbers. Bee behavior, however, can vary, even within the same species. European honeybees tend to be docile and will tolerate approach of their hive to some degree, but they can become provoked. Africanized honeybees *(Apis mellifera scutellata)* are much more aggressive and will defend their hive more proactively. Africanized honeybees were imported to South America in the 1950s to boost honey production, and they have steadily extended their range northward into the southwestern United States. The primary difference between Africanized and European honeybees is their behavior in that Africanized honeybees behave much more aggressively. The effect of an individual stinging event is similar. Subtle wing morphologic differences and DNA testing can also distinguish the bees.

If a person is swarmed by bees or wasps, the best thing for the person to do is

create barriers between himself or herself and the bees. For example, getting behind a door will evade many bees and getting behind another door will evade many more. Older children may be able to outrun bees, which fly at approximately 4 mph and may pursue up to 150 yards. Younger children, however, may be unable to run fast or far enough. Attempting to submerge oneself or another person in water is not recommended because Africanized honeybees will wait until the person surfaces to continue delivering stings. This can result in multiple stings to the airway. A lethal dose of honeybee stings is estimated at 500 to 1200 total stings or 20 stings/kg,[61] but serious envenomation can result from as few as 50 stings (or even fewer after certain species of wasp stings). Sting removal should be done as quickly as possible, regardless of the method of removal. Even a delay of a second or two (to find a knife or credit card) results in a higher dose of venom injected. Contrary to conventional advice, it has been shown that grasping the stinger does not increase the venom dose.

Clinical complications can include hemolysis, coagulopathy, rhabdomyolysis, and liver dysfunction. Delayed toxic reactions have been documented, so 24-hour hospitalization is recommended for pediatric and older patients, as well as patients with underlying medical problems or abnormal laboratory test results within a 6-hour observation period and those with 50 or more stings.[62] Laboratory analysis should be aimed at uncovering the aforementioned clinical complications. Treatment involves IV fluids, intensive care, and possibly dialysis and transfusion as needed. For sensitive individuals, venom immunotherapy in children leads to a significantly lower risk of systemic reaction to stings even decades later.[63]

If an Africanized honeybee hive is suspected, local vector control authorities should be contacted. Avoiding perfume and brightly colored clothes may prevent some stings. Similar to African honeybees, fire ants *(Solenopsis invicta)* are extending their range in the southeastern United States and can cause serious (even fatal) complications after massive envenomation, particularly in infants and small children. These ants typically bite and sting.

CHAPTER 114

Heat Injury

Ofer Yanay, Eli Gilad

PEARLS

- According to the Centers for Disease Control and Prevention, from 1999 to 2003, 3442 deaths were attributable to excessive heat exposure or hyperthermia in the United States.
- With an increased occurrence of heat waves, even in temperate areas, the risk of heat-related illness is rapidly increasing.
- After the onset of heat stroke, the inflammatory response may continue despite adequate control of body temperature. Inflammation, coagulopathy, and progression to multiple organ failure may ensue. New approaches for modulation of the inflammatory response may play a role in treatment of heat-related injury in the future.
- Thorough knowledge and understanding of these disorders may prevent the progression from heat stress to heat stroke.
- Maintaining organ perfusion and rapid cooling are the major treatment goals for patients with heat stroke.
- The central nervous system is particularly vulnerable to heat, with the cerebellum being most susceptible. Pyramidal dysfunction, dysphagia, mental changes (ranging from impaired judgment to delirium and coma), quadriparesis, extrapyramidal syndrome, and neuropathy have all been described.

The interest in heat-related illnesses has grown enormously, largely because of global warming and an increased frequency of heat waves.[1,2] According to the Centers for Disease Control and Prevention, from 1999 to 2003, excessive heat exposure caused 3442 deaths in the United States.[3] During this period, more people died of extreme heat than all other natural disasters combined. Among the pediatric population, neonates and infants are at highest risk, mainly because of poorly developed thermoregulatory mechanisms and total dependence on caregivers to provide adequate protection from excessive heat. Children with mental illness and chronic diseases are at high risk. Adolescents are also at increased risk mostly due to poor judgment or intoxication.

Over the past 2 decades, the understanding of cellular and molecular responses to heat stress has improved dramatically. This is a multiorgan injury resulting from a

complex interplay between the cytotoxic effect of the heat and inflammatory and coagulation responses of the host.[4] Despite better understanding of heat injury pathophysiology, treatment remains supportive, with emphasis on immediate cooling. Prevention and education are still the best tools available in the hands of health care providers to minimize heat-related morbidity and death. This chapter covers the epidemiology, pathophysiology, clinical manifestations, and treatment of nonexertional heat-related illness in the pediatric population.

Definitions

Heat-related illnesses are best regarded as a spectrum of disorders that should be seen as continuum of increasing severity. Several heat-related illnesses may take the form of heat syncope, heat cramps, heat exhaustion, or heat stroke. The following are key terms used in this chapter:

1. *Heat syncope* (fainting) is a mild form of heat illness, which results from physical exertion in a hot environment. In an effort to increase heat loss, the skin blood vessels dilate to such an extent that blood flow to the brain is reduced. This reduction results in symptoms of lightheadedness, dizziness, headache, increased pulse rate, restlessness, nausea, vomiting, and possibly even a brief loss of consciousness. Inadequate fluid replacement, which leads to dehydration, contributes significantly to the problem.

2. *Heat cramps* are painful sustained muscle contractions, most often in the legs or abdominal wall, primarily due to inadequate circulation, dehydration, hyponatremia, and muscle fatigue. Heat has not been shown to directly trigger cramping, and body temperature is usually normal.[5]

3. *Heat exhaustion* is a mild-to-moderate illness due to water or salt depletion (excessive sweat) resulting from exposure to high environmental heat or strenuous physical exercise. The patient may have headache, intense thirst, muscle weakness, dizziness, fainting, nausea, and visual disturbances. Core temperature may be normal or elevated but is less than 40°C. Postural hypotension may occur.

4. *Heat stroke* is a life-threatening emergency that occurs when core temperature exceeds 40°C and the patient is in hypovolemic shock and has central nervous system abnormalities such as delirium, convulsions, or coma. Exposure to environmental heat (classic heat stroke) or strenuous physical exercise (exertional heat stroke) can cause heat stroke. Alternatively, it can be defined as a form of hyperthermia associated with systemic inflammatory response leading to a syndrome of multiorgan dysfunction in which encephalopathy predominates.[4]

5. *Exertional heat stroke* develops in the setting of recreational or occupational exercise. It results from heat production by muscular work, which exceeds the body's ability to dissipate it.

6. *Classic heat stroke* develops in the setting of high ambient temperature. The term *nonexertional heat stroke* has also been used to describe classic high ambient temperature heat stroke.

7. *Heat index* is a measure of the effect of combined elements (eg, heat and humidity) on the body.

8. *A heat wave* is 3 or more consecutive days of air temperatures ≥90°F (≥32.2°C).

9. *Heat-related death:* A death in which exposure to high ambient temperature either caused the death or significantly contributed to it.[6] Because death rates from other causes (eg, cardiovascular and respiratory disease) increase during heat waves, deaths classified as caused by hyperthermia represent only a portion of heat-related death.

Epidemiology

Excessive heat is the second largest contributor to death by natural events in the United States.[7] From 1999 to 2003, an annual average of 688 deaths in the United States was attributable to "excessive heat exposure." Persons aged 15 years and younger accounted for 7% of deaths caused by weather conditions.[8] There is a significant increase in heat-related death rate during heat waves. For example, in 1980, a year with a record heat wave, the death rate was more than three times higher than that for any other year during the 19-year period of 1979 to 1997.[9] Data on heat-related death are imprecise because this condition is underdiagnosed, its definition varies,[4] and many cases of patients with near-fatal heat stroke who survive the acute hospitalization have a high 1-year death rate.[10] There is statistically significant correlation between the number of heat stress illness hospitalizations and the average monthly maximum temperature/heat index.[11] In Saudi Arabia, where the temperature is extremely hot, the incidence of heat stroke varies seasonally, from 22 to 250 cases per 100,000 population.[12] Heat-related illness is reported from subtropical and cold parts of the world as well. In Taiwan, a subtropical country without any history of heat waves, a cluster of heat shock cases was reported during periods of sustained hotter-than-average temperatures.[13] In an observational study in which cold and hot areas in Europe were compared, it was shown that heat-related death started at higher temperatures in hot regions than in cold ones.[14] High ambient temperature and humidity, lack of acclimatization, unavailability of air conditioning, and vigorous physical activity are major predisposing factors for heat-related illness.[15] Within the pediatric population, children younger than 2 years are at higher risk, with specific factors like diarrheal disease, sweat gland dysfunction, child neglect, and underlying chronic or febrile illness contributing. Children left unattended in parked vehicles remain an active problem with an average of 37 fatalities per year in the United States. The majority of cases are children younger than 2 years of age who were "forgotten" by a caregiver or had played in an unattended car.[16] Risk factors for adolescents include poor judgment that may lead to continuation of physical exertion despite warning symptoms. Alcohol and drug abuse and exposure to environmental toxins may put the adolescent at risk. Neuroleptic phenothiazines and tricyclic antidepressants, taken for medical indications; amphetamine and derivatives; marijuana and cocaine; or organophosphates, constituents of many pesticides, may all lead to heat-related illness.[17] Their effect may be due to impaired heat loss or increased heat production.[18] Lithium and fluoxetine (Prozac) may induce heat intolerance.[19]

Pathophysiology and Pathogenesis of Heat-Related Illnesses

Understanding the systemic and cellular pathophysiology of heat-related illnesses involves an appreciation of thermoregulation, physiologic alterations directly related to hyperthermia, acute phase response, and production of heat shock proteins (HSPs). For normal enzymatic and cellular function, it is essential that body core temperature be maintained within a narrow range of about 37°C ± 0.5 to 0.9°C.[17,20] The thermoregulation system, controlled by the preoptic area of the anterior hypothalamus, receives input from thermosensitive receptors in the skin and body core, compares the data with a reference level (the "set point"), and responds to an elevation of 0.3°C[17,21] with activation of heat loss mechanisms.[4,17,22]

Heat dissipation occurs by means of four mechanisms: (1) conduction to the adjacent air and objects, (2) convection through air or liquid, (3) radiation of heat energy, and (4) evaporation. Once activated by the hypothalamus, the efferent heat response is both autonomic and behavioral. Blood delivery to the body surface is increased by sympathetic discharge causing cutaneous vasodilatation. Blood flow may increase 8- to 16-fold, up to 8 L/min.[23] Thermal sweating, in response to parasympathetic discharge, can produce approximately 1 L/h/m^2 of body surface of sweat. Per liter of evaporated sweat, 588 kCal are lost. Secondary to cutaneous vasodilatation and sweating, blood is shunted toward the periphery and visceral perfusion is reduced, especially to the liver, kidneys, and intestines.[21] Rising core temperature will also lead to tachycardia, a high cardiac output state, and an increase in minute ventilation. When ambient temperature equals or exceeds body temperature, conduction, convection, and radiation cease to be effective. Losses of salt and water through sweating may lead to dehydration and salt depletion, resulting in impaired thermoregulation. A combination of high ambient humidity and temperature creates a particularly dangerous situation. With ambient humidity of 90% to 95%, evaporation of sweat essentially stops, and if ambient temperature reaches body temperature, the body can no longer eliminate heat.

Hyperthermia directly induces cellular injury. The severity of injury is cumulative, so exposure to a high temperature for a brief period of time may cause similar injury to an exposure to a lower temperature for a longer period of time.[24] Once extreme temperatures of 49°C to 50°C have been reached, full destruction and cell necrosis occur. At lower temperatures cell death is mainly due to apoptosis.[25]

Acclimatization

Prolonged exposure to a hot environment results in adaptation and tolerance to higher temperature levels. Acclimatization to heat may take several weeks and involves multiple organs. Sweat glands develop increased capacity to secrete sweat, plasma volume is increased, and the renin-angiotensin-aldosterone axis is activated and leads to improved salt conservation. The adaptability of the cardiovascular system is probably the most important single determinant of one's ability to tolerate heat stress.[4,26] Even acclimatized people have definite limitations for heat tolerance. Once driven beyond a critical level, progression to a catastrophic condition may result.

Acute Phase Response

Heat stress initiates cellular acute phase responses aimed at protecting against injury and promoting tissue repair. A variety of cytokines are produced in response to heat stress. Plasma levels of both proinflammatory (tumor necrosis factor alpha [TNF-α], interleukin [IL]-1, and interferon-γ) and antiinflammatory cytokines (IL-6, IL-10, TNF receptors p55 and p75) are elevated in patients with heat stroke.[27-32] Soluble TNF, IL-2, and IL-6 receptors are also elevated in heat stroke.[33,34] It has been shown that the severity of symptoms during heat stroke correlates well with IL-1 and IL-6 levels.[27] Progression from heat stress to heat stroke depends on the time and extent of exposure to severe environmental conditions, but the acute phase response may continue after the patient is cooled. Onset of inflammation may be local with systemic progression,[4,32] involving endothelial cell activation, release of endothelial vasoactive factors,[35] endothelial cell injury, and microvascular thrombosis.[35-37] The gastrointestinal tract may also play a role in the exaggeration of the inflammatory response. Vascular congestion, hemorrhage, thrombosis, and massive loss of surface epithelium in the jejunum were observed in a baboon model of heat stroke.[37] These changes facilitate bacterial and endotoxin translocation and release of mitochondrial DNA fragments, which contribute significantly to the systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS).[38-40] Endothelial cell injury involves activation of both the coagulation and fibrinolytic systems.[41] Heat stress by itself is a procoagulation condition because it causes platelet clumping in small vessels. In addition, heat stress may mediate endotoxemia (following decreased perfusion of the viscera), elevated levels of proinflammatory cytokines, and macrophage activation (via factor VIIa), all of which are well-known inducers of coagulation. Injured endothelium plays an important role in producing and releasing both procoagulant and anticoagulant substances (eg, von Willebrand factor antigen [vWF-Ag], tissue plasminogen activator, and plasminogen activator inhibitor).[35,36] Circulating vWF-Ag, thrombomodulin, endothelin-1, nitric oxide (NO) metabolites, soluble E-selectin, and ICAM-1 (intercellular adhesion molecule 1) are elevated in heat-related illness, creating a clinical picture of disseminated intravascular coagulation (DIC).[35,42-44] Cooling patients with heat stroke reverses only part of these coagulation abnormalities.[41]

Recent studies, using a baboon model for heat stroke, provide more data on pathways of heat stroke–induced tissue injury and cell death. This model can be used to evaluate clinical changes and may be suitable to test immunomodulation therapies to improve outcome.[45]

Systemic Clinical Features

Involvement of multiple organs may be seen, to a certain degree, in heat syncope, heat cramps, and exhaustion. Heat stroke is a systemic disorder. Per definition, core temperature must exceed 40°C, and the patient exhibits hypovolemic shock and central nervous system abnormalities such as delirium, convulsions, or coma.

Central Nervous System

Neurologic dysfunction is a cardinal feature of heat stroke. Brain dysfunction is

usually severe but may be subtle, manifesting only as inappropriate behavior or impaired judgment; more often, patients present with delirium or coma.[22] Seizures may occur, especially during cooling. The central nervous system is particularly vulnerable to heat, the cerebellum being most susceptible.[46] Proton magnetic resonance is a useful tool for evaluating major metabolic changes in the cerebellum after heat stroke.[47] Pyramidal dysfunction, dysphagia, mental changes, quadriparesis, extrapyramidal syndrome, and peripheral neuropathy have all been described.[22,48] No data regarding long-term neurologic outcome in children have been reported.

Cardiovascular

Cardiovascular dysfunction is a common feature of heat stroke.[49] Hypotension and shock may result from splanchnic vasoconstriction and peripheral (cutaneous) vasodilatation aimed to facilitate heat dissipation. Dehydration, combined with redistribution of blood volume, leads to reduction in venous pressure and diastolic filling.[22,49] Circulation is hyperdynamic in these patients, with tachycardia and high cardiac output.[50] Vasomotor tone may remain abnormally low, even after normal temperature and intravascular volume have been restored.

Electrocardiographic changes are common in heat stroke but are nonspecific and include rhythm disturbances (multiform PVCs, VT, and sinus tachycardia) but more frequently QT segment prolongation and ST-T changes.[51] The electrocardiogram (ECG) abnormalities are transient and typically subside with cooling but may require correction of potassium, magnesium, or calcium abnormalities.[52]

Pulmonary

The pulmonary system is not involved in early stages of heat-related illnesses. However, a high incidence (23%-25%) of acute respiratory distress syndrome (ARDS) has been reported in adult patients with heat stroke.[53] Patients with ARDS have poor prognosis, with up to 75% mortality rate. Lung involvement is part of multiple organ dysfunction syndrome and is associated with endothelial dysfunction and DIC.[53]

Renal

Elevated blood urea nitrogen (BUN) and creatinine levels are seen even in mild heat-related disease such as heat cramps.[54] Incidence of acute kidney injury ranges from 5% in classic heat stroke to 25% in exertional heat stroke.[49] Direct thermal injury, hypoperfusion, rhabdomyolysis with myoglobinuria, release of vasoactive mediators, and DIC may all contribute to renal injury.[4,22,55,56]

Gastrointestinal

Gastrointestinal involvement in heat-related disorders occurs mostly during heat stroke secondary to splanchnic vasoconstriction and gut hypoperfusion, leading to cellular injury and bacterial translocation. Gastrointestinal injury plays a significant role in the development of MODS in patients with heat stroke.[4,57,58] The importance of the gastrointestinal system in other forms of heat-related illnesses is not well

studied. Jejunal injury may lead to mild to moderate diarrhea. The liver may be severely injured in heat stroke. This is a metabolically active organ and a major site of heat production. During periods of hyperthermia, liver temperature is among the highest of any organ in the body, putting it at high risk for injury.[24] Abnormal liver function tests may be seen during heat-related illnesses. Elevation of aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyl transpeptidase (γ-GT), lactate dehydrogenase (LDH), and total bilirubin has been described.[10,22,54] Patients with heat stroke demonstrate a typical rise in AST and ALT levels starting 30 minutes from onset, peaking at 48 to 72 hours following injury, with return to normal values after 10 to 14 days.[24,59] Severe liver damage is more common in exertional heat stroke. Fulminant liver failure is rare and usually carries a grave prognosis even with liver transplantation.[60]

Metabolic

Early in the course of heat injury, the most common acid-base abnormality is a mixed nonanion gap metabolic acidosis and respiratory alkalosis. Hypokalemia resulting from respiratory alkalosis, sweat losses, and renal wasting may change to hyperkalemia because of cellular potassium leak. Several hours into the injury the clinical picture changes into a predominantly metabolic acidosis caused by sustained tissue injury.[10,22,61] Hyponatremia is the most common sodium abnormality and is typically asymptomatic. Hypernatremia is rare but associated with worse outcome.[62]

Hematologic

Thrombocytopenia, prolonged clotting time, and DIC are well documented in patients with heat stroke.[4,10,22,37] The pathophysiology of DIC in patients with heat stroke has been previously discussed. Microvascular thrombosis is found in many organs of deceased heat stroke patients. Worsening coagulopathy may occur a few days after cooling. Rapid drop of hematocrit in the first 24 hours following heat stroke is a common feature. This is partially explained by rehydration but is most probably multifactorial. The red blood cell (RBC) half-life is shortened after heat stroke. In addition, RBCs are more fragile following exposure to high temperatures, leading to early removal from the circulation.[24] Hypersegmented neutrophils may be observed in peripheral blood for the first few hours following the onset of heat stroke. The cause for this phenomenon is unclear. These cells are thought to be undergoing changes associated with apoptosis.[24]

Infectious

In the early phase of heat stroke, blood cultures are negative.[63] In one adult study, 27% of patients had positive blood cultures and 25% had positive urine cultures 24 hours after heat stroke.[10] The incidence of positive findings in blood or urine cultures in the pediatric population with heat stroke is unknown.

Treatment

Rapid cooling and maintenance of organ perfusion and function are the major goals

of treatment of heat stroke. Treatment should be started promptly at the scene with removing the patient from the circumstances that led to heat stroke in order to prevent further increase in core temperature.

Adherence to the basic resuscitative guidelines is required, with protection of the airway, management of breathing and monitoring for hypovolemia/shock, and appropriate fluid resuscitation. The most severely affected children have altered mental status, rising body temperature, and hypovolemic shock. After the airway is secured, the child with heat stroke should be moved to a cool environment; clothes should be removed; IV access should be obtained; and a normal saline or lactated Ringer solution bolus should be administered. Fluid resuscitation, besides ensuring organ perfusion, increases heat dissipation and lowers core temperature[64] by improving skin blood flow. Cooling should be started as early as possible with readily available methods. Prompt and appropriate (<39°C) cooling within 30 minutes yields survival rates of 90% to 100% in cases of exertional heat stroke and 40% to 85% in classic heat stroke.[65,66] The rule of "cool first, transport second" applies. This recommendation does not discount the potential for outstanding care at the hospital but rather prioritizes appropriate care in the first 30 minutes after collapse, which is critical for survival.[67-69]

Various cooling methods have been used to promote heat loss, and controversy continues regarding the best cooling technique. Cold/ice water immersion, a cooling method based on conduction, was twice as rapid in reducing the core temperature as the evaporative spray method in patients with exertional heat stroke.[70] The mechanism for this rapid cooling relates to the high thermal gradient between the skin and ice water, leading to a faster heat loss by conductance as compared with evaporation.[71] Ice water is readily available, does not require special equipment, and is suitable for both classic and exertional heat stroke. While some authors regard ice water immersion to be the most efficient cooling method,[72] others claim there is no evidence to support the superiority of any cooling technique, especially in classic heat stroke.[73,74] Critics of immersion point out that it may complicate resuscitation efforts of the comatose child who requires endotracheal intubation, mechanical ventilation, and close observation. Also, it is uncomfortable to the conscious child and may cause shivering and cutaneous vasoconstriction, which is counterproductive. Sponging the patient with ice water while massaging the body and using a fan may overcome some of these disadvantages, yet other studies have shown that keeping the skin relatively warm while allowing evaporation and convection to dissipate body heat is the most rapid way to decrease core body temperature.[75] This can be done with special cooling units,[76] but the concept of keeping the patient "wet and windy" can be easily achieved with the application of tepid water to the skin while a fan is used to keep high air flow and to maintain cool ambient temperature.[77] Hospitals located in high-risk areas may consider using special equipment, but most emergency departments and pediatric intensive care units (PICUs) may use this technique with readily available equipment.

Cooling blankets are widely used in the PICU setting. The effectiveness of this approach was evaluated in patients with fever,[78] and no data are available concerning heat stroke patients. Invasive cooling techniques including iced peritoneal lavage, as well as bladder and gastric lavage, have been suggested and investigated to some extent. Peritoneal lavage is difficult to perform and requires placement of a peritoneal catheter and trained personnel. Evidence for gastric lavage

comes mostly from canine models and was found to have no advantage over evaporative cooling.[74] Recent reports of an intravascular cooling device to control body temperature found the system to be highly effective. However, there are only case reports regarding its use on patients with heat stroke, and it cannot be recommended at this point.[79,80] Antipyretics are not recommended for treatment of heat stroke.[74] These drugs lower body temperature by normalizing the elevated hypothalamic set point. In heat stroke, the elevated body temperature reflects failure of cooling mechanism rather than abnormal set point. Acetaminophen and salicylates should be avoided due to their potential to aggravate coagulopathy and hepatic injury.[73,74] Dantrolene has been used successfully for malignant hyperthermia and neuroleptic malignant syndrome. There are conflicting data regarding its effectiveness in heat stroke.[81-83] Once a core body temperature of 39°C has been achieved, active cooling may be stopped. This end point appears to be safe in terms of mortality. Unfortunately, a safe end point for long-term morbidity (particularly for neurologic outcome) has not yet been established.[73] Induced hypothermia has not been evaluated for effectiveness with heat stroke. A recent study looking at therapeutic hypothermia after out-of-hospital cardiac arrest in children showed no benefits in survival with good neurologic outcome.[84] Hence, it is highly unlikely to be beneficial in pediatric patients with heat stroke. All pediatric patients with heat stroke should be observed in the PICU, even if respiratory support is not required. Basic laboratory workup should include electrolytes (including sodium, potassium, magnesium, phosphate, and calcium), renal and liver function tests, complete blood count, creatine kinase, and coagulation studies. Urine output should be followed closely, and a urine sample should be sent for myoglobin analysis. Biomarkers of damage linked to heat-related illness are nonspecific with limited diagnostic value and accurate assessment of organ damage. High-mobility group box 1 protein (HMGB1) level at admission in patients with exertional heat stroke was found to be an indicator of the severity of illness and a useful mortality predictor.[85] As previously mentioned, patients with heat stroke may continue to deteriorate even after body temperature is normalized because of the inflammatory response. There are no specific guidelines for treating patients with heat stroke–related MODS.

Prevention is still the best treatment for heat-related illness. Whenever possible, people should acclimatize themselves to hot weather. Physical activity should be undertaken during cooler hours, and water intake should be increased. Children should never be left unattended in a closed car, especially during hot weather. Physicians' awareness and knowledge may promote diagnosis of early forms of heat-related illness, thus preventing progression to heat stroke. On a national level, a good weather forecasting system and air-conditioned shelters for vulnerable populations may decrease heat-related morbidity and death during heat waves.[86,87]

CHAPTER 115

Accidental Hypothermia

Björn Gunnarsson, Christopher M.B. Heard

PEARLS

- Accidental or unintentional hypothermia is a potentially lethal complication of exposure to cold. It can occur as a result of exposure to cold air, water immersion/submersion, or snow burial.
- Risk factors include accidents, neglect, toxins, mental disorders, and violence.
- Information about the duration and severity of cold exposure, scene details, and any other associated injuries may help in the selection of the appropriate facility and rewarming methods.
- Many organ systems are affected by hypothermia. There is a marked depression of cerebral blood flow and oxygen use.
- Rescuers should initiate resuscitation on all patients with hypothermia unless a patient has a frozen chest or any other obvious nonsurvivable injury. The hallmark of rescue in all individuals with hypothermia is prevention of further heat loss, careful transport, and rewarming. Avoiding excess activity and rough movements of patients with hypothermia is important because this may precipitate cardiac dysrhythmias.
- Various techniques have been used for in-hospital resuscitation from deep hypothermia, but no controlled studies in which rewarming methods are compared exist and rigid treatment protocols cannot be recommended. Active external rewarming has been shown to be effective. Extracorporeal rewarming of blood is the preferred method, however, to resuscitate patients with hypothermia and cardiac arrest or cardiovascular instability.
- Prediction of patient outcome is difficult. The decision to terminate resuscitative efforts must be based on the unique circumstances of each case.

There is no uniform classification of accidental or unintentional hypothermia, but it can be categorized as mild (35°C–32°C), moderate (32°C–28°C), severe (<28°C), or profound (<24°C or <20°C).[1-3] The Swiss staging system of hypothermia is based on clinical findings at the scene that roughly correlate with core temperature.[4-7] The stages correspond to the four categories mentioned earlier, as well as stage V: death due to irreversible hypothermia (<13.7°C?). This is a serious and in many cases preventable health problem that can cause marked depression of bodily functions, to

such degree that live victims may appear clinically dead.[3,8,9] Each organ system may be affected.[10] However, our understanding of accidental hypothermia is based largely on case reports and studies in animals, as controlled studies of serious hypothermia in humans are not available for obvious reasons.

Physiology

Humans have a high capacity to dissipate heat but a relative poor capacity to increase heat production, and they rely heavily on environmental regulation in the form of clothing and warm shelter to maintain normal body temperature. The body can compensate to a great degree for mild hypothermia. The hypothalamus sends signals that produce cutaneous vasoconstriction, increased muscle tone, and metabolic rate. When muscle tone reaches a certain level, shivering thermogenesis begins. The clinical manifestations depend on the severity, acuity, and duration of temperature reduction; the patient's age; premorbid conditions; and superimposed disease states. Children are more susceptible to hypothermia than adults because of a large surface area relative to body mass and less subcutaneous tissue. Neonates have a capacity for nonshivering thermogenesis, primarily by metabolism of brown fat; however, this is at the cost of greatly increased oxygen consumption. Neonates are therefore extremely sensitive to relatively minor deviations from a neutral thermal environment.

Central Nervous System

Cerebral oxygen requirement decreases with cooling and mentation is progressively impaired. Mild hypothermia may be associated with confusion, dysarthria, and impaired judgment.[10] Deep tendon reflexes are depressed at core temperature below 32°C because of slowed peripheral nerve conduction. As body temperature drops, many victims no longer complain of cold. Shivering thermogenesis ceases at about 31°C. Pupillary responses decline and dilated unreactive pupils may be noted at temperatures below 30°C. Victims may experience hallucinations and sometimes paradoxically remove their clothes. The electroencephalogram shows abnormal activity at temperatures less than 32°C, and at 20°C the electroencephalogram may appear consistent with brain death.[11]

Cardiovascular

The initial cardiovascular responses are vasoconstriction, tachycardia, and increased cardiac output. Further hypothermia results in decreased pacemaker and conduction velocity, causing bradycardia, heart block, and prolongation of PR, QRS, and QT intervals.[12] The myocardium becomes irritable, and atrial fibrillation is common when core temperature is below 32°C and the risk of ventricular arrhythmias is substantial below 30°C.[8,12,13] The electrocardiogram may show characteristic J or Osborne wave following the QRS complex (Fig. 115.1).[14-17] The presence of this wave is not pathognomonic for hypothermia and has no prognostic implications.[12,18] Myocardial contractility, cardiac output, and systemic blood pressure are often decreased dramatically in hypothermic victims. These changes may be persistent

during and after rewarming.[19] Hypovolemia due to cold-induced diuresis and capillary leakage may potentiate the problem.[11,19,20]

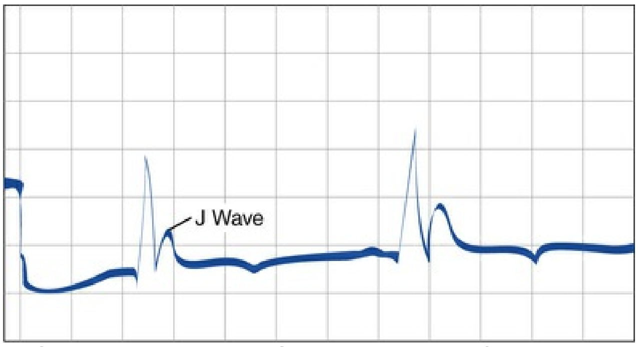

FIG. 115.1 Characteristic J or Osborne wave of hypothermia closely follows QRS. It may be mistaken for T wave with narrow QT interval if the true T wave is not appreciated. Slightly rounded peak distinguishes it from R′ of bundle branch block. (From Welton D, Mattox K, Miller R, et al: Treatment of profound hypothermia. JAMA 240:2291, 1978.)

Respiratory

Hypothermia affects tissue oxygenation through several complex physiologic mechanisms. Initially, the respiratory rate may be increased. As hypothermia worsens, the respiratory center becomes depressed and hypoventilation causes carbon dioxide retention, although the carbon dioxide production decreases with increasing hypothermia. Respiratory arrest is a late occurrence. Suppression of cough and mucociliary reflexes leads to atelectasis and pneumonia. Oxygen delivery to the tissues is further compromised by shifting of the oxyhemoglobin dissociation curve to the left.[11] Blood gas analyzers warm blood to 37°C before analysis.[21] In patients with hypothermia, arterial blood gases show higher oxygen and carbon dioxide levels and a lower pH than a patient's actual values. The best approach to interpretation is to compare the uncorrected blood gas values with the normal values at 37°C (Alpha-Stat strategy).[13,22-24]

Renal

Renal injury may occur either because of hypothermia or during the rewarming process.[25] The mechanisms involved in cold diuresis may include peripheral vasoconstriction and blunted response to antidiuretic hormone. Renal vasoconstriction and ischemia to the kidney may lead to oliguria and acute tubular necrosis in those with severe hypothermia. Progressive hypokalemia develops during hypothermia, probably because of the shifting of potassium from the extracellular to intracellular compartment, and significant hyperkalemia may develop during rewarming.[26,27] The electrocardiogram (ECG) manifestation of hyperkalemia may be obscured or attenuated by hypothermia.[12] Renal replacement therapy may be required for renal failure and has also been used for rewarming.[28,29]

Coagulation

Hypothermia inhibits the intrinsic and extrinsic pathways in the clotting process. The degree of coagulopathy, however, is often underestimated because dynamic coagulation tests are generally performed at 37°C in the laboratory. Bone marrow suppression and splenic sequestration can lead to thrombocytopenia, and platelets become dysfunctional.[11,13] This leads to increased bleeding tendency, and the combination of hypothermia and trauma carries a grave prognosis.[30,31]

Treatment

The hallmark of rescue in all individuals with hypothermia is prevention of further heat loss, careful transport, and rewarming.[3,11] Wet clothes should be removed, and the individuals should be insulated and shielded from wind and cold.[5] Paying special attention to the head and neck is important because radiant heat loss from those areas can be profound.

Collapse of deeply hypothermic victims around the time of rescue may be explained by further cooling, circulatory collapse due to hypovolemia, or arrhythmias, sometimes triggered by procedures, such as central venous catheterization.[5,8,13] Sudden changes in hydrostatic conditions may contribute during extrication of victims from cold water. This has been attributed to sudden fall in blood pressure and inadequate coronary blood flow, precipitating ventricular fibrillation.[32,33] Victims should therefore be kept horizontal during rescue, if possible.[33]

Resuscitation

Detecting signs of life in patients with deep hypothermia may be difficult, and the rescuer should therefore assess breathing and then pulse for 60 seconds.[5,8] Chest compressions should be started immediately if the patient is pulseless with no detectable signs of circulation and may have to be continued for hours before extracorporeal rewarming can be started.[8,34-37] Victims in cardiac arrest have survived when resuscitation after rescue was delayed by as much as 70 minutes.[38] The advantages of endotracheal intubation outweigh the minimal risk of triggering ventricular fibrillation with the procedure. If cervical spine injury is suspected, the neutral position must be maintained with manual cervical stabilization. Care should be taken not to overventilate the patient's lungs because this can increase ventricular irritability.[39] Defibrillation can be tried up to three times for ventricular tachycardia or fibrillation. If arrhythmia is resistant to three shocks in a patient with deep hypothermia, then further defibrillation attempts should be deferred until core temperature is ≥30°C.[5,40] However, a systematic review of animal models performing resuscitation from ventricular fibrillation in severe hypothermia revealed much higher return of spontaneous circulation rates in studies administrating vasopressor medications.[41] The hypothermic heart may also have a reduced response to pacing and cardioactive medications, but evidence for medication efficacy and risk of accumulation to toxic levels, if administered repeatedly, is limited and based mainly on animal studies.[5,41-46] The European Resuscitation Council Guidelines for Resuscitation 2015 recommend withholding resuscitation medications until the

patient has been warmed to core temperature ≥30°C and doubling the interval between doses compared with normothermic patients.[5] The 2010 American Heart Association Guidelines, on the other hand, are less clear on this and conclude that it may be reasonable to consider administration of vasopressor during cardiac arrest caused by hypothermia.[9]

Rewarming

The rewarming of victims who are conscious with mild hypothermia and still able to shiver can be achieved with passive techniques (eg, blankets, wool cap, warm shelter). Active external rewarming with chemical heat packs or forced warm air can be useful in the prehospital setting to prevent further heat loss in victims with moderate hypothermia. Some researchers claim that standing and exercising immediately after rescue may be hazardous as this may accentuate core temperature afterdrop.[2] The term *core temperature afterdrop* refers to a continued decrease in core temperature with potential for clinical deterioration of a victim after rescue. There are two mechanisms behind this. One is the inevitable equilibration of temperature between the periphery and core.[47] It follows that the magnitude of afterdrop is greater if cooling is rapid because the temperature gradient between the surface and core is greater.[48] The other mechanism is increased blood flow to the cold periphery and return of cold blood to the core (convection), possibly causing cardiovascular instability.[49] Any intervention that causes increased blood flow to the periphery, including exercise, can potentially accentuate the afterdrop, but the significance of this in the clinical management of hypothermia victims is debated.[2,3,8,47,50] However, avoidance of excessive activity and abrupt movements of any hypothermia victim seems prudent. Attempts to rewarm the victim of hypothermia should not delay transport to hospital.[5] It is difficult to rewarm hypothermic patients during transport, and no specific recommendations can be given. The use of mechanical cardiopulmonary resuscitation devices should be considered if body size fits the device, as this increases safety and may improve outcome.[5,8,34,51-53] Fig. 115.2 shows a simple triage and management algorithm, a slight modification of an algorithm in use in the Northern Norway Regional Health Authority.[54]

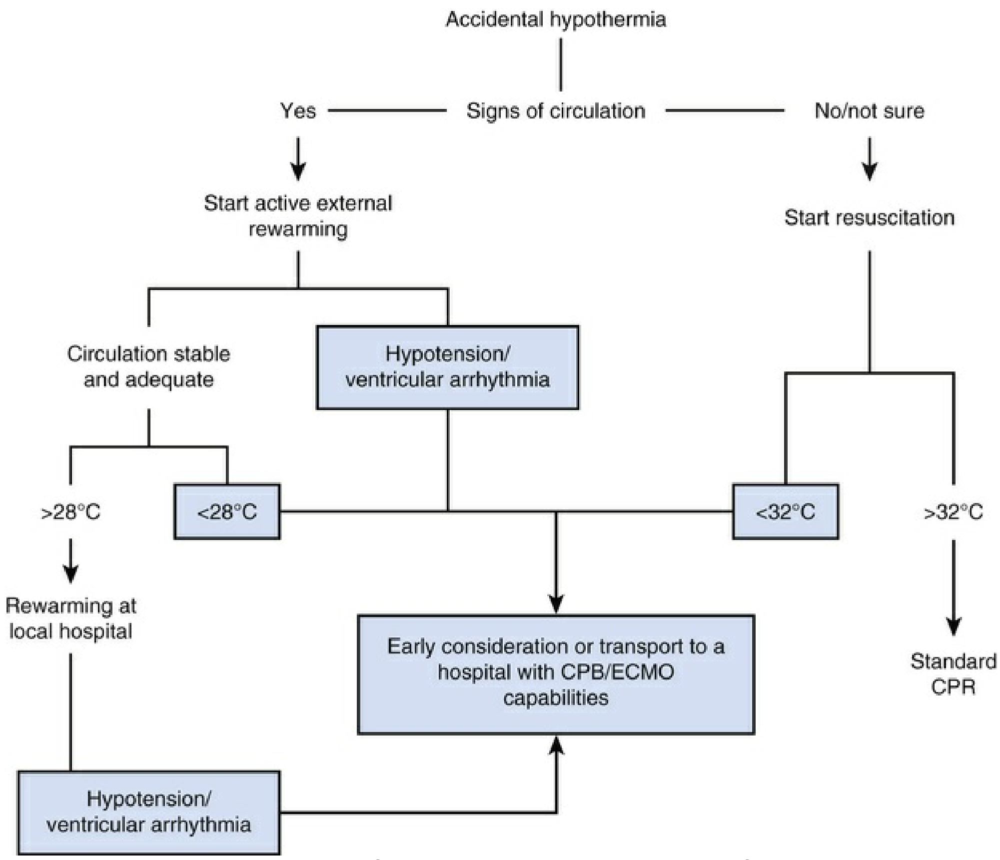

FIG. 115.2 Algorithm for management and triage of victims with accidental hypothermia.

Several techniques have been used in-hospital for active rewarming of hemodynamically stable patients, but no controlled clinical trials in which rewarming methods are compared exist. This includes warming with forced air, warm humidified gases, warmed IV fluids (up to 42°C), and lavage of gastric, peritoneal, pleural, or bladder cavities with warmed fluids (40°C).[3] There are many reports of successful use of different techniques in children with severe hypothermia, even with cardiac arrest.[55-63] Thoracic lavage using two large chest tubes can accomplish a temperature increase of 3°C to 6°C/hour and warming with forced air (Bair Hugger) can also be quite effective (approximately 2°C/hour).[64] However, victims with a core temperature <28°C, hemodynamic instability, or cardiac arrest should be taken directly to a center capable of extracorporeal rewarming, unless trauma or other coexisting conditions mandate transport to a closer hospital.[5,6,8,24,36,65-69]

Extracorporeal rewarming may be undertaken with traditional cardiopulmonary bypass (CPB) or venoarterial extracorporeal membrane oxygenation (VA-ECMO). The latter may be preferred as prolonged support may be necessary and outcome may be better, compared with CPB.[5,8,70,71]

There are no formal studies of care after ROSC in hypothermic victims, and management should follow usual standards.[3] Inotropic support with levosimendan or milrinone should be considered, rather than relying on β-adrenergic agents, which may have reduced effects during hypothermia and rewarming.[44,45,72] Therapeutic hypothermia for at least 24 hours may be indicated. Continuous electroencephalogram and early neuroimaging may help estimating brain injury

severity, diagnose seizure activity, and detect injury requiring neurosurgical intervention.[73]

Outcome

Knowledge about epidemiology, management, and outcome is limited. It may help to apply the concept of sufficient-cause model to elucidate this problem.[74] Accidental hypothermia is frequently the cause of neurologic injury and death but by itself not a sufficient cause, as demonstrated by the fact that good neurologic recovery is possible after prolonged hypothermic cardiac arrest in adults with initial core temperature as low as 13.7°C and cardiopulmonary resuscitation up to almost 7 hours.[37,75] There are also many reports of successful resuscitation of children and adolescents with severe hypothermia.[24,58-61,63,69,76] The term *accidental hypothermia* is too imprecise. One must specify the type of accidental hypothermia (eg, exposure, immersion, or submersion), severity (eg, cardiac arrest or hemodynamic instability), duration, age and condition of the victim, whether there is comorbidity, and methods of resuscitation and rewarming. Yet however we define severe accidental hypothermia, it will not cause neurologic injury or death in everyone exposed, within some limits. So who is less susceptible to the effect of hypothermia and what are the limits? We know that good neurologic outcome is unlikely when asphyxia precedes hypothermia.[65,68,77,78] However, there are many reports of dramatic recovery after prolonged cold-water submersion of pediatric patients.[59,61,63,79-82] Cases of good outcome in drowning victims are generally associated with water temperatures at, or near, freezing and hypothermia on arrival to hospital. It is therefore reasonable to assume that good outcome in these cases must be associated with cerebral hypothermia.[22,66,81,83] Rapid cooling of the pediatric body, due to large surface area relative to body mass and little subcutaneous tissue, may offer protection of the brain against anoxia.[23,79] Furthermore, it is thought that rapid cooling of the brain may largely depend on repeated aspiration of cold water into the lungs.[32,36,66,83,84] However, reviews from Finland and Canada did not find an association between water temperature or age and outcome.[81,85,86]

The Præstø Fjord boating accident in Denmark provides important insight.[24] One adult and 13 adolescents were rescued after prolonged immersion in 2°C saltwater, half with spontaneous circulation and the other half in circulatory arrest with their head submersed, drowning by definition.[87] Interestingly, six out of seven with spontaneous circulation were females and five out of seven without spontaneous circulation were males, suggesting that females were less susceptible to profound hypothermia, despite similar fitness level and clothing. This was likely explained by higher body fat percentage in the females, supported by the fact that mean body mass index was higher in the group that did not develop circulatory arrest. All seven with circulatory arrest were transported to the same ECMO facility with ongoing life support. Blood gas analysis revealed a median pH of 6.61 (range 6.43 to 6.94) and lactate of 21.0 mmol/L (range 9.4 to 24.0). None of the patients had hyperkalemia, and none developed multiple organ failure. All were long-term survivors, one with severe cognitive dysfunction and the other six with mild-to-moderate dysfunction. This unfortunate accident demonstrated high survivability with well-functioning chain of survival and advanced in-hospital technology. However, brain resuscitation of asphyxiated victims still has a poor prognosis.[73] Comorbidity, physical condition

of victims, and course of accidental hypothermia are likely to impact outcome. Management of snow avalanche victims is outside the scope of this chapter, but it highlights the importance of asphyxia. Victims found without an air pocket have poor prognosis, whereas extracorporeal rewarming has been successful in cases where asphyxia did not predominate.[6,36,38,71,88,89]

Reported mortality and the need for prolonged organ support for victims with severe hypothermia and circulatory arrest treated with CPB or VA-ECMO vary widely.[24,36,65,66,68,69,71,90]

Systemic edema and cardiorespiratory failure may lead to death despite aggressive support.[19,71] Severe coagulopathy, acidosis (venous pH <6.5), and hyperkalemia (>10 mmol/L) are among factors that have been associated with poor outcome.[36,90-92] An admission serum potassium of 11.8 mmol/L in a 31-month-old girl with extreme hypothermia after exposure to cold weather is the highest reported value in a survivor.[76] Serum potassium >12 mmol/L on admission is probably a reason to terminate resuscitation.[8,36] Clinical judgment must be exercised, and it must be kept in mind that children with accidental hypothermia have tremendous potential for good outcome despite a catastrophic presentation. A reasonable approach, in most cases, is to resuscitate and warm the child aggressively until the core temperature reaches 32°C and continue resuscitation for 30 more minutes.[93] At that point, if no signs of life are present and the victim is not responding to aggressive life support measures, termination of resuscitation may be indicated.

We still have much to learn about susceptibility to hypothermia and limits of survivability, and we clearly need better tools for prognostication and brain resuscitation. Quality research on accidental hypothermia is necessary, and one hopes that data from the International Hypothermia Registry, which receives reports from over 50 centers worldwide, may increase our insight into this important health problem.[94]

CHAPTER 116

Drowning

Ajit A. Sarnaik, Mary W. Lieh-Lai, Ashok P. Sarnaik

PEARLS

- Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid.
- Deaths from unintentional drowning have declined, but drowning remains a major cause of death in children.
- Aspiration of water and other debris during drowning can cause pneumonia and acute respiratory distress syndrome.
- In some cases, an underlying cause of drowning should be investigated, such as seizure disorder or primary cardiac illness.
- The major source of long-term morbidity for drowning survivors is neurologic, as injuries to other organ systems are generally reversible.
- The protective effect of cold water temperature in drowning victims has recently been called into question.
- Cardiopulmonary resuscitation at the scene in drowning victims should be performed in the traditional ABC sequence, as opposed to the CAB sequence.
- The outcome of drowning victims depends largely on the success of resuscitative measures at the scene of injury.

Of all the clinical entities encountered in a pediatric ICU, drowning accidents are among the most tragic. Within minutes, previously healthy children with hopeful futures die or are left severely incapacitated with no chance of meaningful cognition. The parents, once full of dreams for their children, are suddenly beset with tremendous grief and guilt because in most instances, the accident could have been prevented by simple measures.

Definitions

The definition of drowning events continues to be a great source of confusion. Although there has been some improvement in the use of appropriate terms, review of literature shows that terms such as *near drowning* and *suffocation by submersion in water* remain in use. The use of terms other than *drowning* makes it difficult to

analyze and compare studies and outcome. Similar issues involving terminology and definitions existed in the resuscitation literature. These problems were addressed in 1990 by a group of investigators who met at the Utstein Abbey on the island of Mosteroy, Norway, by coming up with a standardized format for reporting of research involving out-of-hospital cardiac arrest.[1] In June 2002, the World Congress on Drowning was convened to develop a more standard definition of drowning using the Utstein style for uniform reporting of data and to make recommendations regarding preventive measures and care. The Congress was initiated by the *Maatschappij tot Redding van Drenkelingen* (Dutch Organization to Rescue People from Drowning), an organization established in Amsterdam in 1767 to promote drowning awareness in the Netherlands.[2] The final recommendation of the Congress was to define *drowning* as the process of experiencing respiratory impairment from submersion/immersion in liquid. Immersion is defined as having face and airway covered in water, whereas submersion is defined as the entire body including the airway being underwater. The definition implies that a drowning victim develops an air-liquid interface that prevents him from breathing air. A recommendation was made to abandon all other terms such as near drowning and secondary drowning. Outcome is described according to death or survival, and survivors can be further categorized according to neurologic function.[3] Papa et al.[4] performed a systematic review of definitions for drowning accidents in 2005 and identified at least 43 publications where various definitions of drowning were used (Table 116.1). They concluded that there is a need to use a single, uniform definition of drowning and supported the one recommended by the Utstein Focus World Congress on Drowning.

TABLE 116.1

Summary of Categories and Terms Used to Describe Drowning

Terms	Explanation
Specific Categories	
Primary versus secondary	"Secondary drowning" is delayed death from drowning, due to complications, OR death occurring in minutes to days after initial recovery.
Wet versus dry/with aspiration versus without aspiration	"Dry drowning" or "without aspiration" is defined as laryngeal spasm with no or little aspiration of water OR from respiratory obstruction and asphyxia from a liquid medium. "Wet drowning" or "with aspiration" indicates that aspiration of fluids has occurred.
Warm versus cold water	"Cold water drowning" is defined as drowning in an outside body of water during the autumn, winter, and early spring months with a patient core temperature of ≤32°C on arrival to the emergency department. Some use water temperature <20°C
Salt versus freshwater	Describes kind of water in which incident occurred.
Active versus passive (or silent)	"Active" refers to a witnessed drowning event in which victim makes some motion. In "passive," victim is found motionless.
Intentional versus nonintentional	Describes cause.
Fatal versus nonfatal	Describes outcome.
With and without hospitalization	Describes whether or not victim was admitted to hospital.
Specific Circumstances	
Iceberg phenomenon	"Iceberg phenomenon" is described as people who have been submerged but have subsequently not died from drowning.
Immersion frigida	"Immersion frigida" is defined as death from cooling in water.
Immersion syndrome/immediate disappearance syndrome	Occurs when syncope is provoked by sudden contact with water at least <5°C presumably from bradycardia, tachycardia, or arrhythmia.
Save	Rescue of victim from water by someone who perceived individual to be a potential victim of submersion injury.

From Papa L, Hoelle R, Idris A. Systematic review of definitions for drowning incidents. Resuscitation. 2005;65:255-264, Table 2, p. 260.

Epidemiology

Deaths from unintentional drowning in United States have gradually declined from 1999–2010 according to the National Center for Health Statistics, perhaps because of greater emphasis on water safety.[5] Australia has reported a similar decline in deaths due to drowning in recent years. The greatest decline (46%) occurred in infants under the age of 1 year followed by persons aged 5 to 19 years (30%).[5] Despite these encouraging data, drowning remains a major cause of death from unintentional injury in young children. A total of 49,762 deaths from drowning occurred, with an average of 4147 deaths per year. The average annual death rate from drowning for males of 2.2 per 100,000 population was three times that for females. The death rate for males was highest among those aged 1 to 4 years. In 2013, drowning was reported as the number one cause of death from unintentional injuries (393 of 1316) in children aged 1 to 4 years. Of these, 52.2% occurred in a swimming pool.[6] Drowning is the second most common cause of death from unintentional injuries in children aged 5 to 9 years (15.5%) and in children aged 10 to 14 years (12%), second to motor vehicle accidents. While the majority of drowning deaths occurred in a swimming pool in children aged 1 to 9 years, drowning deaths in older children aged 10 to 14 years occurred in natural bodies of water. In 2003, the World Health Organization estimated that there were 450,000 deaths attributable to drowning each year.[7]

In 2011, Shields et al.[7] reported on drowning events in portable above-ground pools. Data were obtained from the US Consumer Product Safety Commission. There were 209 fatal and 35 nonfatal drowning cases in children younger than 12 years. Ninety-four percent of the victims were younger than 5 years of age, and 56% were boys. Portable above-ground pools pose a special risk because they are small, inexpensive, and installed by the consumer, plus they do not generate the same feeling of risks associated with in-ground pools. In some instances, water depth was as low as 2 inches (wading pools). In addition, it is uncommon to provide barriers for portable above-ground pools. Ladders cannot be moved to block access, and wading pools do not come with safety covers.

Children younger than 1 year most often drown in bathtubs, buckets, or toilets. While child abuse should be suspected in these situations, up to 35% of children between the ages of 10 and 18 months were shown to be able to climb into a bathtub.[8,9] Drowning in a bathtub should therefore not be considered as a priori evidence of child abuse. Others at risk for bathtub drowning are those with seizure disorders.[10] Drowning is highest during the summer months and on weekends. Most children who drown were last seen inside the home, in the care of one or both parents, but left unsupervised for less than 5 minutes.[11]

Other important risk factors in drowning deaths include failure to wear a life jacket and alcohol use. In 2006, the US Coast Guard reviewed reports of boating incidents. Of the 500 people who drowned, 9 out of 10 were not wearing life jackets.[12] Alcohol use is involved in up to half of adolescent and adult deaths associated with water recreation.[13] Ethanol and other neurotropic agents can diminish manual dexterity, impair judgment, and increase risk-taking behavior.

Recent alcohol consumption by supervising adults may also contribute to drowning accidents involving children.[14] Expert swimmers have also been known to drown during underwater swimming. The practice of hyperventilation to prolong the duration of underwater swimming is particularly hazardous in this regard because significant hypoxemia may result in loss of consciousness before hypercarbia stimulates respiration.[15] Although an uncommon cause of drowning, arrhythmia from long QT syndrome (LQTS) should be suspected and investigated for after syncope, seizure, or cardiac arrest during or after swimming.[16]

The key to prevention includes careful supervision of children and education of the public regarding drowning prevention and the hazards of drowning. Children playing near or in water should always be supervised by a responsible adult who is not distracted by any other activity. Alcohol should be avoided before or during swimming, boating, and while supervising children. A four-sided, self-closing, self-latching fence at least 4 feet high that completely separates the house and play area of the yard should be installed around household pools. Those who are in or around natural bodies of water should wear US Coast Guard–approved life jackets irrespective of distance to be traveled, size of boat, or swimming ability.

Pathophysiologic Considerations

The sequence of events after submersion has been described by Karpovich in animal studies.[17] The drowning process has been described by the World Congress on Drowning as a continuum that begins when the victim's airway lies below the surface of the liquid (Fig. 116.1).[3] After an initial period of voluntary breath-holding, reflex laryngospasm is initiated by the presence of liquid in the oropharynx or larynx. Hypoxia, hypercarbia, and acidosis ensue and when sufficiently severe, result in lessening of laryngospasm and breathing of liquid into the lungs. The amount of liquid aspirated varies considerably among the victims. Once the liquid reaches the alveoli, a pernicious sequence develops characterized by marked disruption in pulmonary architecture and pathophysiologic alterations. These include surfactant washout, atelectasis, pulmonary edema, pulmonary hypertension, and continuing intrapulmonary shunting. The victim may be rescued at any time during the drowning process thus aborting or minimizing lung injury.

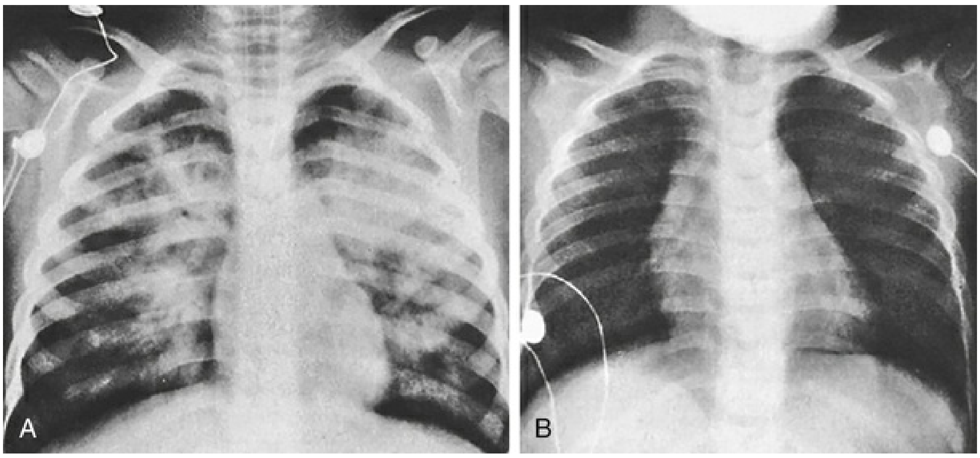

FIG. 116.1 Near drowning with and without aspiration. Radiographs show

a patient with severe pulmonary edema (A) and another without significant fluid aspiration (B). (From Ciullo JV, ed. Clinics in Sports Medicine. Philadelphia: WB Saunders; 1986.)

The single most important and prognostically significant consequence of drowning is decreased oxygen delivery to the tissues. A number of clinical variables determine the magnitude of hypoxia and the subject's ability to withstand it. The pathophysiology of drowning is thus closely integrated with the genesis of hypoxemia and its effects on various organ functions. A working knowledge of these pathophysiologic principles and multiorgan involvement is extremely helpful in directing therapeutic strategies for optimum survival.

Type of Aspirated Fluid

Although the differences between changes in electrolytes and blood volume after seawater and freshwater aspiration have been emphasized in the past, they are of little clinical significance in patients who survive long enough to be transported to a medical facility.[18] Aspiration of more than 11 mL of fluid per kg of body weight is required for blood volume to be altered, and aspiration of more than 22 mL/kg is necessary before significant electrolyte changes occur.[19,20] Most drowning victims aspirate less than 3 to 4 mL of fluid per kilogram of body weight. Hypervolemia resulting from freshwater aspiration is rarely a problem. Most drowning victims are hypovolemic regardless of the type of aspiration because of increased capillary permeability resulting from asphyxia and the loss of protein-rich fluid into the alveoli.

Pulmonary Effects

Functional residual capacity (FRC) is the only source of gas exchange at the pulmonary capillary level in the submerged state. Increased metabolic demands from struggling, breath-holding, a depletion of FRC from breathing efforts, and aspiration of fluid into the lungs all result in seriously compromised O_2 uptake and CO_2 elimination, with consequent hypoxia and hypercarbia. Between 10% and 15% of drowning victims have severe laryngospasm after submersion, resulting in fatal asphyxiation without aspiration of significant water into their lungs (Fig. 116.1). A combined respiratory and metabolic acidosis caused by hypercapnia and anaerobic metabolism is often encountered. Patients without significant fluid aspiration recover from asphyxia rapidly if they are successfully resuscitated before cardiac arrest or irreversible brain damage occurs. Aspiration of fluid, however, results in persistently abnormal gas exchange. Aspiration of as little as 1 to 3 mL per kilogram body weight results in profound impairment of gas exchange.[20,21] Soon after the aspiration of fluid, there is an elevation of $PaCO_2$ and a fall in PaO_2 as a result of airway obstruction, hypoventilation, and impaired gas exchange between alveoli and pulmonary capillary blood. With adequate resuscitation, normocapnia or even hypocapnia is usually achieved while hypoxemia persists, indicating a significant ventilation/perfusion mismatch and diffusion defect leading to intrapulmonary shunting and venous admixture.[22]

The surfactant system of the lung is affected differently in freshwater and

seawater aspiration.[23] Freshwater aspiration results in marked disruption of the surfactant system of the lung resulting in alveolar instability and atelectasis. Seawater, because of its hypertonicity, draws water into the alveoli. Although the surfactant may be diluted by the presence of seawater in alveoli, its surface tension properties are not significantly altered. Zhu et al.[24] examined serum levels of pulmonary surfactant-associated protein (SP-A) and lung weights in 53 victims of fatal drowning. They showed significantly heavier lungs in those who drowned in seawater versus freshwater suggesting an osmolar effect. Although they found no difference in serum SP-A, intra-alveolar aggregates of pulmonary surfactant associated protein were noted more frequently in those who drowned in freshwater. This is likely related to the disruption of surfactant noted in freshwater drowning. Karch demonstrated marked changes in the pulmonary vasculature in rabbits within 30 minutes of aspiration of both freshwater and salt water.[25] Mitochondrial swelling and disruption of pulmonary vascular endothelial cells were consistently observed in these experiments. Clinically, pulmonary abnormalities are encountered in both fresh and seawater aspiration. These are consistent with pronounced injury to alveoli and pulmonary capillaries resulting in increased membrane permeability, exudation of proteinaceous material in alveoli, pulmonary edema, decreased lung compliance, and increased airway resistance. The extent of these abnormalities may not be manifested fully for several hours after the submersion episode and may be progressive in nature. Acute respiratory distress syndrome (ARDS) is the hallmark of delayed pulmonary insufficiency resulting from aspiration in drowning. This is characterized by progression of ventilation-to-perfusion mismatch, alveolar-capillary block, increased capillary permeability, and pulmonary edema. Reduced FRC and diffusion barrier resulting from accumulation of fluid and inflammatory cells in the alveoli and interstitium further accentuate hypoxemia. Aspiration of stomach contents and other debris such as sand, mud, and algae may also impair gas exchange. Bacterial pneumonia resulting from aspiration of contaminated water may further contribute to pulmonary insufficiency. Factors that contribute to drowning-associated pneumonia include aspiration of vomitus or aspiration of contaminated material from water that may contain sewage. Water temperature plays a role, with warmer temperatures predisposing to a higher number of organisms. The chemical composition of the water such as pH, salt content, and presence of organic and inorganic substances influence bacterial growth as well. Organisms include aerobic gram-negative bacteria such as *Klebsiella* spp. and *Pseudomonas* spp. and gram-positive bacteria including *Streptococcus pneumoniae* and *Staphylococcus aureus*. Fungi such as aspergillus have been reported to cause drowning-associated pneumonia as well. The diagnosis of pneumonia is based on clinical parameters such as fever, leukocytosis, respiratory cultures, and new infiltrates on chest radiographs.

Understanding the alterations in pulmonary mechanics is important in order to provide the necessary support in the least injurious fashion. Predominant manifestations are those of ARDS complicating the drowning event. Although pulmonary involvement is often bilateral and diffuse, there is considerable inhomogeneity, with some areas more affected than others. Overall, lung compliance is reduced, necessitating higher inflation pressures to maintain adequate tidal volume (Vt). Low Vt at low FRC leads to a vicious cycle of atelectasis, decreased compliance, and further reduction in Vt. Critical opening pressure necessary to begin alveolar inflation is increased. Appropriate positive end-expiratory pressure (PEEP)

needs to be administered to maintain the necessary FRC for adequate oxygenation and ventilation above the critical opening pressure. Airway resistance is relatively less affected or only minimally elevated unless there is airway obstruction from aspirated debris. Time constant, a product of compliance and resistance, reflects the time needed for pressure equilibration between the proximal airway and alveoli to occur. In ARDS, time constant is decreased, allowing for quicker approximation of pressures at these sites during the inspiratory and expiratory phases of the mechanical ventilation. Relatively large tidal volume (10–12 mL/kg) is associated with greater ventilator-induced lung injury in ARDS, whereas smaller tidal volume (6 mL/kg) is associated with less volutrauma. Because of the short time constant, prolongation of inspiratory time to improve oxygenation and increasing the respiratory rate for CO_2 elimination are often effective options during mechanical ventilation. A more detailed description of management of ARDS in drowning appears later in this chapter.

Cardiovascular Effects

Profound cardiovascular instability is often encountered after a severe drowning event, and it poses an immediate threat to survival after the initial rescue. The hypoxemia that occurs due to ventilation-perfusion mismatch can cause life-threatening dysrhythmias such as ventricular tachycardia, ventricular fibrillation, and asystole. The two determinants of oxygen delivery, namely cardiac output and arterial O_2 content, can be adversely affected by the drowning event. A decrease in PaO_2, if sufficiently severe, decreases oxygen saturation and therefore arterial O_2 content. This decrease in arterial O_2 content can cause a decrease in myocardial oxygen delivery, which contributes to worsening cardiac output and decreased myocardial perfusion pressure. Smooth muscle contraction banding in the media of major coronary arteries and local ventricular myocytes with focal myocardial necrosis have been described after a drowning episode.[26,27] Cytosolic calcium overload and oxygen-derived free radicals have also been implicated in the mechanism of myocardial injury after resuscitation after cardiac arrest.[28] Cardiogenic shock may result from hypoxic damage to the myocardium. Metabolic acidosis may further impair myocardial performance. Additionally, therapeutic application of PEEP decreases venous return and right and left ventricular preload. Right ventricular afterload is also increased by structural pulmonary microvascular damage and humoral inflammatory mediators involved in ARDS. The right ventricle is anatomically designed to tolerate increased preload, but it is not as tolerant of high pressures and afterload as the left ventricle. If pulmonary hypertension is severe enough, left ventricular preload further decreases due to right ventricular failure. These factors, as well as the excessive capillary permeability of pulmonary and systemic capillaries, result in hypovolemia and decreased left ventricular filling pressures. The end result is that of inadequate supply of oxygen to tissues to meet their metabolic demands.

Central Nervous System Effects

Due to a lack of metabolic substrate reserves, the brain depends on continuous oxygen delivery. Metabolic failure can begin within seconds after an immediate

disruption in circulation. Hypoxia, if sufficiently prolonged, causes profound disturbances of central nervous system (CNS) function. The severity of brain injury depends on the magnitude and duration of hypoxemia and cerebral hypoperfusion, as well as on mechanisms of secondary brain injury. The most important components of brain-specific management include prompt rescue, early and successful resuscitation, and mitigation of secondary injuries.

Following restoration of adequate cerebral oxygen delivery after the initial hypoxemia and/or hypoperfusion after drowning, there are several mechanisms of secondary brain injury at the tissue, synaptic, and cellular level. At the tissue level, increased intracranial pressure (ICP) and alterations in cerebral blood flow can adversely impact local tissue oxygen delivery. At the synaptic level, the excitotoxic neurotransmitter glutamate can cause an imbalance in the neuronal supply and demand. Delayed neuronal death occurs due to cellular responses to hypoxia and subsequent reperfusion, leading to complex pathways of prosurvival and prodeath signals. Intracellularly, accumulation of cytosolic calcium, neuronal energy failure associated with DNA damage and repair, and generation of oxygen free radicals can all contribute to secondary neuronal death.

Several developmental factors render the neurologic effects of pediatric cardiac arrest different from those of adults. Brain injury from sudden cardiac arrest, which more commonly occurs in adults, results when cerebral blood flow suddenly stops. In contrast, brain injury from drowning, along with most causes of pediatric cardiac arrest, is caused by asphyxia. Cerebral oxygen delivery continues for some period of time and progressively decreases because of hypoxemia and decreased cerebral blood flow. Cardiac arrest may occur but is usually preceded by this period of decreased oxygen delivery. Neurologic injury is similar to that of other causes of pediatric asphyxia, including foreign body airway obstruction, apnea, asthma, and suffocation. Approximately 13% of all children with cardiopulmonary arrest survive to hospital discharge, and only 9% if the arrest occurred outside the hospital.[29] Studies in humans and animals indicate that there are several developmental differences in excitotoxic pathways. In the neonatal period, there is increased vulnerability to NMDA receptor activation[30] and glutamate toxicity,[31] as well as heightened capability for apoptosis, which, albeit an important process of normal brain development, may render the immature brain vulnerable to neuronal loss after an insult.[32] In addition, a developmental difference exists in cerebral blood flow (CBF) after cardiac arrest. In adult models of cardiac arrest, global hyperemia is present for 15 to 30 minutes after return of spontaneous circulation (ROSC) followed by delayed hypoperfusion that persists for several hours. In an immature animal model of a brief asphyxial cardiac arrest, hyperemia is observed for 10 minutes after ROSC followed by restoration of baseline CBF, whereas prolonged cardiac arrest is followed by hypoperfusion and blood pressure–dependent CBF.[33]

Effects on Other Organ Systems

Drowning victims are at significant risk for the development of hypoxemia and/or ischemia, particularly in the face of cardiac or respiratory arrest. These factors increase the risk for multiple organ dysfunction syndrome (MODS). In addition to neurologic injury and acute lung injury, hepatic and renal injuries have been observed. Typpo and colleagues[34] reported on the incidence of multiple organ

dysfunction syndrome on Day 1 in children admitted to the PICU. Of the 18% of children who developed MODS on the first day, 30% to 35% had an unfavorable neurologic outcome. In 2015, Mtaweh et al.[35] reported on the patterns of MODS in children after drowning. Pediatric Logistic Organ Dysfunction Score-1 (PELOD-1) and Pediatric Multiple Organ Dysfunction Score (P-MODS) were calculated for the first 24 hours of admission. Of the 60 children, 39 of them (65%) were in respiratory arrest and 21 of them (35%) were in cardiac arrest at the scene. Of these, 15 remained pulseless on arrival to the PICU, 6 of whom died. Seventeen of 60 patients had severe neurologic injury. Of the children who developed MODS, 52% (21/40) had cardiac arrest and 48% (19/40) had respiratory arrest. Children who suffered cardiac arrest had much more significant organ dysfunction that included neurologic, respiratory, hepatic, and renal systems. Of those children who developed acute kidney injury (3/60), one child required continuous renal replacement therapy and hemodialysis.

Mammalian Diving Reflex

A certain degree of protection against hypoxia in drowning may occur in the form of a response similar to the diving reflex observed in seals and other air-breathing diving mammals. The ability of these animals to remain submerged for periods up to 20 minutes is due to a remarkable redistribution of blood flow that occurs after diving underwater. While the heart, brain, and lungs remain adequately perfused, blood flow to tissues resistant to hypoxia (ie, gastrointestinal tract, skin, and muscle) is markedly reduced. Significant bradycardia occurs with a reduction in cardiac output. Such a response, albeit quantitatively less, is also observed in humans after total body immersion.[36] The mammalian diving reflex acts as an oxygen-conserving adaptation in response to submersion. It has been proposed that this reflex is most active in infancy and is potentiated by fear and low water temperature.[37] A combination of marked bradycardia and impalpable pulses resulting from vasoconstriction may make the victim appear dead at a time when mouth-to-mouth resuscitation could be life-saving.[36] Clinical studies involving children and adults have failed to demonstrate an efficient diving reflex in response to cold water submersion.[38,39] Young children had a significantly decreased breath-hold duration and consequently a weaker dive response compared with older children and adults.[39] The role of the mammalian diving reflex in enabling children to withstand prolonged cold water submersion thus remains controversial.

Preexisting Associated Conditions

An underlying etiologic mechanism should be explored depending on a given clinical scenario involving unexplained drowning. Children with seizure disorders are at greater risk for submersion accidents. Similarly, an occurrence of vasovagal syncope or a hypoglycemic episode during swimming may be the underlying factor responsible for drowning. Occult cardiomyopathy or a cardiac arrhythmia should also be considered in an unexplained drowning event. An episode of drowning might be the first manifestation of long QT syndrome (LQTS). Ackerman et al.[40] studied blood samples or archived autopsy tissue samples in 35 cases of autosomal-dominant LQTS. Six of these patients had a personal history or extended family

history of near drowning. All of these patients were found to have LQTS causing mutations in *KVLQT1,* whereas such an abnormality was found in only 3 of remaining 29 patients who did not have a personal history of submersion episode.[40] Thus swimming appears to be a gene-specific (*KVLQT1)* arrhythmogenic trigger for LQTS. Diagnosis of inherited LQTS allows for identification of other family members with similar affliction.[5] Yoshinaga et al.[41] showed that face immersion in cold water results in abnormal lengthening of the QT interval in children identified with nonfamilial LQTS, and such children could potentially be at risk of a life-threatening arrhythmia during swimming. More recently, Albertella et al.[16] described the presentation of outcome of water-related events in children with LQTS. Of the 10 children identified with LQTS and a documented history of water-related syncope, 9 had LQTS type 1. Seven were swimming at the time of the syncopal event. Factors leading to arrhythmias during swimming in patients with LQTS are thought to include facial immersion in cold water and the dive reflex that causes a fall in heart rate, competing with epinephrine release from exercise. Patients with LQTS should avoid swimming and diving and any medications that can prolong the QT interval. Beta blockers have been shown to reduce the risk of sudden death in LQTS by 75%.[42]

Hypothermia in Drowning

Hypothermia has been shown in numerous animal and human studies to mitigate many of the processes involved in the development of secondary brain injury from both trauma and asphyxia. Positive effects of hypothermia for the injured brain include a decrease in cerebral metabolic rate, intracranial pressure (ICP), excitotoxic neurotransmission, cytotoxic edema, generation of deleterious oxygen-derived free radicals, and the cerebral hyperemia, which can cause ischemia/reperfusion injury and further increase ICP. Potential effects of therapeutic hypothermia are discussed later in the chapter. The effects of hypothermia may apply to drowning injury, as good outcomes have been reported in children submerged in ice water (<5°C) for prolonged periods.[19,43] It appears that if hypothermia is protective in drowning, rapid cooling in ice water is necessary, as a lesser degree of hypothermia in warmer water does not offer cerebral protection.[44] It is also possible that a publication bias exists in reporting of cold water drowning, as cases with good outcome are more likely to be published than cases with poor outcome.[45] Indeed, more recent studies call into question the protective effects of hypothermia in drowning. Quan studied more than 1000 child and adult open-water drowning victims and did not find a protective effect of cold water but rather estimated submersion duration was the most powerful predictor of outcome.[46] In this study, young age was also a predictor of good outcome, which may reflect the capacity of children to become hypothermic faster and possibly benefit from its neuroprotective effects. The elderly, as well as the young, are most susceptible to hypothermia. Its protective effects notwithstanding, hypothermia by itself poses a direct threat to survival due to its adverse effects on cardiac rhythm.

Management

Because the full extent of CNS injury cannot be adequately determined immediately after the rescue, all drowning victims should receive aggressive basic and advanced

life support at the site of the accident and in the emergency department (ED). It cannot be overemphasized that the major determinant of survival and maximal brain salvage is prompt and effective management of hypoxemia and acidosis. In this context, the management in the immediate postdrowning period is of paramount importance. The success or failure of cardiopulmonary resuscitation (CPR) at the site of the accident often determines the outcome.[47,48] The issue of the duration of submersion in relation to the success of resuscitation is often raised. Although asphyxia for longer than 5 minutes frequently results in significant brain injury, this should not be a consideration in deciding whether or not to initiate on-site resuscitation. The emotional excitement surrounding the accident makes it impossible to accurately estimate the duration of hypoxia.

Management at the Scene

Ensuring the adequacy of the airway, breathing, and circulation is the goal of basic life support after the initial rescue. In cases of inadequate airway and cardiopulmonary status, CPR must be instituted immediately. The fundamentals of basic life support are the same after drowning as for any other situation requiring CPR; however, some practical aspects are worth considering. Unlike the out-of-hospital cardiac arrests in adults, cardiac arrests from drowning in children are initiated by hypoxia due to disconnection of atmosphere from the airways and lungs. It is important therefore that CPR is performed in the traditional airway-breathing-circulation (ABC) rather than circulation-airway-breathing (CAB) sequence.[49] The aim of resuscitation at the scene is to prevent irreversible tissue injury from prolonged hypoxia and ischemia. The victim should be removed from the water as soon as possible. Mouth-to-mouth breathing should be performed even while in the water if it can be accomplished. Less than 0.5% of drowning victims suffer from cervical spine injuries. Cervical spine immobilization in the water is indicated when head and neck injury is strongly suspected such as in accidents involving diving, water-skiing, and surfing.[50] In such situations, the preferred airway opening maneuver is anterior displacement of the jaw, rather than extension of the neck. Chest compressions should not be attempted in water because they are ineffective and waste valuable time. Prolonged attempts to remove water from the lungs are futile and may hinder ongoing ventilatory support. Heimlich and Patrick[52] have recommended the use of subdiaphragmatic pressure in drowning victims to remove water from the airway. In addition to the fact that most drowning victims aspirate relatively small amounts of water, there is no evidence to suggest that the Heimlich maneuver can remove aspirated freshwater or pulmonary edema fluid.[48] On the other hand, such patients frequently swallow large amounts of water. Consequently, increased abdominal pressure may result in regurgitation of gastric contents into the oropharynx and aspiration into the tracheobronchial tree.[53] Any debris observed in the oropharynx should be removed before initiation of mouth-to-mouth breathing. Presence of airway obstruction caused by a foreign body should be suspected if effective chest expansion cannot be accomplished with appropriate ventilatory technique. A subdiaphragmatic thrust in such a situation would be indicated. As soon as the equipment becomes available, ventilation with 100% oxygen via bag-valve-mask device should be initiated for patients who are not breathing adequately. Pressure used during resuscitation to inflate the lungs of

drowning victims may have to be higher than anticipated because of reduced compliance of the edematous lungs. A PEEP valve should be used if available. Overinflation should be avoided, however, because this can lead to pulmonary barotrauma and overdistention of the stomach with regurgitation and aspiration of gastric contents. In patients who are too obtunded to maintain airway protection, who exhibit hypoxia, or who are otherwise unable to maintain oxygenation despite bag-valve-mask ventilation, endotracheal intubation should be performed. Pulse oximetry provides valuable information, especially during transport of such patients. An automatic external defibrillator device (AED), if available, should be applied if return of spontaneous circulation is not accomplished with standard measures.

Emergency Department Evaluation and Stabilization

As with any form of accidental injury, other forms of associated trauma must be considered. Children who slip and fall into the pool may sustain external head injury such as abrasions, lacerations, and contusions. Occasionally, profuse bleeding from scalp lacerations may be sufficient to aggravate hypovolemic shock. In bathtub drowning, or in instances where child abuse is suspected, fractures and other evidence of previous injury should be looked for. In adolescent victims, drowning is frequently associated with illicit drug or alcohol use. When appropriate, urine and blood toxicology tests should be performed. Spinal injuries should be suspected in diving, water-skiing, and surfing accidents involving young adults.[48]

The need for hospitalization should be determined by the severity of the drowning episode and clinical evaluation. All patients with a history of drowning should be observed in the ED for at least 4 to 6 hours. Those with insignificant history and normal physical examination may be treated safely as outpatients.[54] Patients with respiratory symptoms, decreased O_2 saturation indicated by pulse oximetry or blood gas determination, and altered sensorium should be hospitalized.

The extent of cerebral hypoxia can be quantified by Conn's criteria as category A (awake), category B (blunted consciousness), and category C (comatose). Category C is subclassified into C_1 (decorticate), C_2 (decerebrate), and C_3 (flaccid).[55] The Glasgow Coma Scale (GCS) has also been proposed to estimate severity of neurologic dysfunction.[56] Both the GCS and Conn's classification are helpful in determining management and judging response to therapy and for prognostication.

Maintaining adequate airway, respirations, and peripheral perfusion with continued attention to oxygenation, ventilation, and cardiac performance should take priority. Electrocardiographic monitoring and arterial blood gas determination should be performed as soon as possible. Ventricular dysrhythmias, asystole, and hypotension may be encountered during the early resuscitation phase. The standard CPR techniques also apply to the drowned child. Patients with respiratory acidosis and hypoxemia, as well as those who are unconscious with significant respiratory distress or poor respiratory efforts, require intubation and mechanical ventilation. Early use of PEEP is effective in reversing hypoxemia. Because pulmonary edema is not caused by hypervolemia in drowning, diuretics are not helpful and, in addition, may exacerbate the prevalent hypovolemia. Therefore pulmonary edema after near drowning is best treated mechanically with positive pressure breathing and PEEP rather than diuretics. Hypovolemia is commonly encountered in the early

resuscitation phase. Isotonic crystalloids (20 mL/kg) or colloids (10 mL/kg) infused over 15 to 20 minutes should be used for intravascular volume expansion. Additional volume expansion can be carried out on the basis of clinical and hemodynamic status. Administration of large amounts of hypotonic fluid is contraindicated because such solutions are ineffective for intravascular volume expansion. Furthermore, the resultant decrease in serum osmolality may exacerbate cerebral edema. In the face of continued hypotension and/or impaired peripheral perfusion after appropriate intravascular volume expansion, inotropic/vasopressor support may be necessary. Central venous pressure (CVP) monitoring is extremely helpful for ongoing assessment and management of intravascular volume. Metabolic acidosis resolves with improvement of oxygenation and tissue perfusion. Radiologic studies should include a chest radiograph to determine the presence or absence of pneumothorax or pneumomediastinum. Unless head injury is suspected, computed tomography scan of the head is usually not necessary because early findings are often normal even in the face of severe hypoxic damage.[57]

Two areas of clinical care in both the ED and ICU remain unsettled: glycemic control and maintenance of body temperature. Both hypoglycemia and hyperglycemia are independent risk factors for adverse neurologic outcome. Prevention and treatment of hypoglycemia are extremely important, yet the role of tight glycemic control is debatable. It is reasonable to maintain blood sugar between 80 and 160 mg/dL. The issue of controlling body core temperature also deserves mention. Most case reports of remarkably good outcome are described in the settings of cold or icy water drowning. Benefits of therapeutic hypothermia, however, have not been proven. A recently published study showed that therapeutic hypothermia does not offer added protection compared with normothermia in pediatric out-of-hospital arrests.[58] However, there may be special considerations in drowning victims because most are relatively hypothermic at the time of rescue. After return of spontaneous circulation, a reasonable approach is to not rewarm the victim aggressively as long as the core temperature is between 32°C and 34°C. Rewarming should occur at a rate no greater than 0.5°C/hour. Hyperthermia (>37°C), on the other hand, must be prevented or treated aggressively if present.[59,60] Severe bradycardia and intense vasoconstriction associated with marked hypothermia (<32°C) may make drowning victims appear dead. However, resuscitative efforts should be continued while normalizing body temperature.

Management in the ICU

The drowning victim can suffer insults to many organ systems, including the brain, lungs, cardiovascular system, liver, and kidneys. Because the major contributor of mortality and long-term morbidity is cerebral hypoxic-ischemic injury, management in the ICU should focus on supporting these organ systems as they relate to the brain. Continued attention to oxygenation and ventilation status and cardiac performance is essential. Acute respiratory distress syndrome can occur as a result of aspiration injury, pneumonia, and surfactant deficiency or dysfunction. Pulse oximetry is readily available and provides a good indication of oxygen saturation and may especially be useful in continuous monitoring of patients who may develop pneumonia or ARDS. However, because of the nature of the oxygen-hemoglobin dissociation curve, pulse oximetry does not accurately reflect changes in PaO_2

greater than 70 mm Hg. Both hypoxemia and hyperoxemia have been associated with poor outcome after cardiac arrest. Maintenance of oxygen saturation between 94% and 98% and PaO_2 between 70 and 100 are reasonable goals. The cerebral vasculature of the injured brain is reactive to changes in $PaCO_2$. Hypercapnia increases cerebral blood volume and can raise ICP. Conversely, arterial hypocapnia decreases cerebral blood flow and therefore cerebral oxygen delivery. Thus ventilation should be titrated to achieve $PaCO_2$ around 40 torr. To monitor these effects, arterial and central venous pressure monitoring are necessary in most patients who require intensive care. A useful parameter to monitor is mixed venous oxygen saturation (SvO_2). Provided arterial oxygen content and oxygen consumption remain constant, SvO_2 is a useful indicator of changes in cardiac output.

The need for endotracheal intubation and different ventilatory strategies should be determined on an individual basis and by clinical judgment. Respiratory acidosis, PaO_2 less than 60 torr in FiO_2 greater than 0.5, clinical signs of impending respiratory fatigue, and depressed level of consciousness are the most common indications for mechanical ventilation. Lung injury may not peak until at least 24 hours, so weaning from mechanical ventilation should not occur before then. Early use of PEEP and supplemental oxygen are extremely effective in reversing hypoxemia.

The goal of mechanical ventilation is to provide adequate gas exchange to ensure tissue viability while minimizing the inevitable ventilator-associated injury from oxytrauma, barotrauma, volutrauma, and ineffective tracheobronchial toilet. Ventilatory strategy should take into account the major alterations in pulmonary mechanics. As noted earlier, most children who drown have decreased FRC, compliance, and time constant and increased critical opening pressure. Salutary effects of PEEP are from maintaining alveolar stability, alveolar recruitment, and increasing FRC. It stabilizes the relatively softer chest wall of a child thus minimizing chest wall recoil and further decrease in FRC. PEEP also displaces intra-alveolar water into interstitial and perilymphatic spaces, resulting in decreased venous admixture and improved compliance. Excessive PEEP can result in decreased venous return and cardiac output, pulmonary overdistention and decreased compliance, and barotrauma. Maintenance of normovolemia is an important consideration in patients receiving PEEP. Furthermore, excessive PEEP can decrease cerebral venous drainage and increase cerebral blood volume and intracranial pressure. Overdistention can also impair ventilation, and the subsequent increase in pCO_2 can increase ICP. Thus PEEP should be titrated to maintain lung recruitment, ventilation, and oxygenation while maintaining hemodynamics.

It is now recognized that in patients with acute lung injury and ARDS, ventilation with lower tidal volume (6 mL/kg) results in improved survival compared with those ventilated with a larger tidal volume (12 mL/kg).[61] Various ventilatory strategies may be used to minimize barotrauma in a patient with ARDS while maintaining adequate gas exchange. The underlying principle is to recruit lung volume by application of optimum PEEP to maintain FRC above the critical opening pressure and ventilate with tidal volume approximating 6 to 7 mL/kg. Both pressure-controlled and volume-controlled strategies can be used using this principle. The authors recommend pressure-controlled ventilation with a relatively low peak airway pressure and prolonged inspiration while still allowing adequate time for

complete exhalation. Alternatively, pressure-regulated volume control mode can also be used to deliver a preset tidal volume with minimum possible inflation pressure. The level of PEEP can be optimized by gradual increments depending on its effects on increasing PaO_2/FiO_2 ratio. The ability of modern ventilators to display exhaled tidal volume and graphic display of flow, pressure, and volume waveforms has enabled the clinician to adjust mechanical ventilatory support according to individual alterations in pulmonary mechanics. Optimal PEEP as evidenced by improvement in dynamic compliance can be determined by measuring exhaled tidal volume at varying levels of PEEP. When PEEP exceeds critical opening pressure or the lower inflection point on the pressure/volume curve, dynamic compliance improves. Ventilatory rate, inspiratory/expiratory times, and peak airway pressures can also be adjusted according to their effects on dynamic compliance and by ascertaining the return of expiratory flow to baseline. In patients without CNS injury and intracranial hypertension, the technique of permissive hypercapnia can be used to minimize barotrauma in a patient with ARDS. This involves using lower inflation pressures or tidal volume and accepting higher levels of PCO_2 as long as pH remains near normal.

High-frequency ventilation is another strategy that can be used in the management of hypoxic respiratory failure. This mode of ventilation uses a relatively high mean airway pressure while minimizing excessive fluctuations in pressures during the respiratory cycle. High-frequency ventilation is a safe and effective modality in the treatment of severe acute respiratory failure that is unresponsive to conventional mechanical ventilation.[62,63]

While extracorporeal life support (ECLS) has been used for rewarming in patients with severe hypothermia following drowning in cold water, the routine use of ECLS for the treatment of ARDS associated with drowning is less clear. The presumed benefit of ECLS is the provision of lung rest to mitigate barotrauma and oxygen toxicity in patients who do not improve despite maximum ventilatory support. Because of the paucity of reports on its use, criteria for ECLS in drowning with refractory cardiovascular or respiratory dysfunction should be similar to other disease states.

Recent studies have shown the benefits of the administration of exogenous surfactant in children with ARDS.[64] Evidence indicates disruption of surfactant, particularly in those children who drown in freshwater. Exogenous surfactant administration may be a reasonable therapeutic modality in children who develop ARDS after drowning and who have persistent pulmonary insufficiency in spite of aggressive respiratory support including high-frequency ventilation. While there are no randomized controlled trials examining the benefits of surfactant administration in patients with ARDS following drowning, there are case reports that describe improvement in oxygenation following instillation of exogenous surfactant.[65-67]

Pneumonia can occur early after a drowning injury because of the aspiration of contaminated water or endogenous organisms. However, it can be misdiagnosed early because of the radiographic appearance of water and inflammation. There is no evidence to suggest that "prophylactic" antibiotics help prevent drowning-associated pneumonia and may lead to the selection of resistant organisms.[68] Furthermore, drowning in swimming pools rarely results in pneumonia.[69] However, fulminant *S. pneumoniae* bacterial sepsis and pneumonia have been described shortly after a severe drowning injury. It is therefore reasonable to institute broad-spectrum

antibiotic therapy in patients with positive sputum cultures, fever, sepsis, or severe cardiopulmonary deterioration, especially when this occurs after a period of stability.[70] The use of corticosteroids for aspiration pneumonia is probably of no benefit.[71]

Once the patient is successfully resuscitated, the severity of encephalopathy is the main determinant of mortality and morbidity from drowning. With improved techniques of cardiopulmonary support, delayed deaths resulting from pulmonary insufficiency are becoming less frequent. CNS injury is by far the most important cause of death and long-term functional impairment among the immediate survivors of drowning accidents. Measures for cerebral protection after drowning have been used by several investigators.[37,55] The emphasis of such modalities is on managing cerebral edema, controlling intracranial hypertension, and decreasing cerebral metabolic requirements, with the use of fluid restriction, diuretics, mechanical ventilation, hypothermia, steroids, barbiturates, and muscle paralysis. However, studies have failed to demonstrate beneficial effects of such therapy in improving the outcome of hypoxic encephalopathy associated with drowning.[72] Furthermore, a significant increase in infections and pulmonary insufficiency was observed in association with therapeutic hypothermia in this setting. Pentobarbital has the theoretic advantage of decreasing cerebral oxygen demand. However, induction of pentobarbital coma, although effective in controlling intracranial hypertension, has not improved the neurologic outcome of comatose children.[72-74] The role of cerebral edema and intracranial hypertension in potentiating CNS injury in otherwise salvageable children is questionable in this setting. The authors' experience suggests that significant intracranial hypertension is not commonly encountered in the early postdrowning period, whereas late, uncontrollable intracranial hypertension carries an unfavorable prognosis.[75] Additionally, satisfactory control of intracranial hypertension is not necessarily associated with improved outcome.[72,73,75] It appears that the occurrence of cerebral edema and intracranial hypertension 2 to 3 days after drowning is a reflection of the early hypoxic injury rather than a manifestation of a reversible process. Late, persistent, intracranial hypertension associated with a comatose state is of ominous significance and is almost always associated with an unfavorable outcome.[75]

The most practical tool of neuromonitoring is the standard neurologic examination. The vast majority of patients who are awake and interactive in the ED survive neurologically intact. However, deterioration is possible due to delayed neuronal loss and cerebral edema in the first several days after injury. Admission neurologic examination by itself is not predictive of outcome. Large and unreactive pupils portend a severe hypoxic ischemic injury and a poor neurologic prognosis. Components of the examination that should be performed serially include pupillary reactivity, level of consciousness, brain stem reflexes, and motor function. On the basis of cardiac arrest data, poor pupillary reactivity after 24 hours and absent motor activity at 72 hours portend a severe hypoxic ischemic injury and a poor neurologic prognosis. Currently, the routine use of ICP monitoring in children with hypoxic-ischemic encephalopathy after drowning is not recommended. The emphasis of management of a comatose child in the immediate postdrowning period should be on maintaining adequate oxygenation/ventilation, oxygen delivery, and avoidance of hypotonic fluid overload. Pathophysiologic changes from asphyxia, as well as various therapies aimed at cerebral salvage such as barbiturates and osmotic

diuresis, adversely affect myocardial performance.[76] Cardiovascular support with maintenance of intravascular volume and the use of inotropic agents is often necessary to maintain optimum organ perfusion in patients who have suffered a significant hypoxic-ischemic insult.

The neuroprotective properties of hypothermia that have been extensively demonstrated in laboratory studies suggest potential merits as a therapy in some children, including victims of drowning. A randomized controlled trial of therapeutic hypothermia has shown benefits in neonatal hypoxic-ischemic encephalopathy.[77] Two randomized control trials in adult cardiac arrest showed the use of moderate hypothermia improved neurologically intact survival.[78] In the late 1970s Conn showed improvement in neurologic outcome in children who were victims of submersion injury, using “HYPER” therapy that included hypothermia, hyperventilation, neuromuscular blockade, barbiturates, and dehydration.[37] However, therapeutic hypothermia has fallen out of favor, as subsequent studies in pediatric drowning showed that not only did hypothermia not improve outcome, it increased infectious complications and only improved survival to a vegetative state.[72,79] It is possible that studies designed with a different depth and/or duration of hypothermia or rewarming procedure may yield different results. Hypothermia has been shown to decrease ICP in trauma,[80] but rebound intracranial hypertension can occur during rewarming.[81] In cases of cold water drowning, although the patient should be actively warmed to prevent arrhythmias and secondary infections, once a core body temperature of 30°C is achieved, warming should not exceed 0.5°C/hour to prevent rises in cerebral blood flow and ICP, ischemia/reperfusion injury, and fever. However, given the lack of positive randomized controlled trials in pediatric asphyxial arrest or in drowning, hypothermia cannot be strongly recommended as a therapy at this time.

Prognosis

The outcome of drowning victims depends largely on the success of resuscitative measures at the scene of injury. Survival is extremely poor among drowning victims who have sustained a cardiac arrest and comparable with other causes of out-of-hospital cardiac arrest.[82] Other markers of poor outcome in pediatric drowning victims include generalized edema[83] and respiratory arrest.[84] Patients who are successfully resuscitated and who are conscious on arrival at the hospital have an excellent chance of intact survival.[47,85,86] Some groups have suggested that the neurologic prognosis is poor if the patient arrives comatose in the ED, whether or not he or she receives aggressive “brain resuscitation” (ie, goal-directed therapy for optimization of cerebral perfusion pressure).[87] However, even children who are successfully resuscitated may have subtle neurocognitive impairment. In a review of 64 drowned and resuscitated children, 57% had neurologic dysfunction and 40% had low full-scale intelligence quotient on long-term follow-up.[88] With improvements in intensive care medicine, pulmonary injury can be successfully managed in most patients. Occurrence of cardiac arrest and length of submersion most consistently appear in the literature as negative prognostic factors in pediatric drowning. However, most existing studies on pediatric drowning are not readily generalizable because they are mostly retrospective in nature, narrow in scope, and small in subject numbers, while encompassing many years in which there is variability in

patient care.[89] Therefore it is difficult to ascertain from the literature risk factors impacting outcome following pediatric drowning, let alone therapeutic options. Our experience suggests that the absence of cognitive function 72 hours after the hypoxic episode is strongly associated with either death or survival in a persistent vegetative state.[75] As previously mentioned, severe hypothermia immediately at rescue has been shown to influence outcome favorably even after prolonged submersion; however, not all hypothermic drowning victims are fortunate to escape serious neurologic damage.

A database review of 267 cases of serious pediatric drowning events in Massachusetts in 1994–2000 showed better outcome in younger age groups, females, and Hispanic children and worse outcomes in African-American children.[90] These data likely reflect differences in time to first responder arrival and suggest that prevention strategies should take into account differences in age, gender, and ethnicity.

CHAPTER 117

Burn and Inhalation Injuries

Phylicia D. Dupree, Amy T. Makley, Richard J. Kagan

PEARLS

- The accurate estimation of the extent and depth of burn injury is crucial for appropriate resuscitation and maintenance of adequate urine output and hemodynamics.
- Early endotracheal intubation of pediatric burn patients with suspected inhalation injury is essential to reduce morbidity and mortality.
- Enteral nutrition via oral intake or postpyloric feeding tube early post burn is recommended.

Burns account for approximately 1 million injuries annually in the United States alone,[1] of which 450,000 seek medical treatment, 400,000 require hospitalization, and roughly 3400 die in fire-related accidents every year.[2] Approximately 29% of these burns occur in children younger than 16 years of age,[3] with children younger than 5 years representing 19% of reported burn cases.[2] Infants and children are a unique patient population that demonstrates increased susceptibility to death.[4] Young children have not only limited physiologic reserves but also patterns of injury that are very different from adults. Although thermal burns secondary to scald or flame are by far the most common etiologies in children and adults, injuries from chemical and electrical burns may be devastating and require early recognition and treatment. Pediatric burn diagnosis and management are complex and require the expertise of a multidisciplinary team.

With appropriate resuscitation and nutritional support, prompt recognition and management of inhalational injury, and early surgical treatment, mortality rates can be minimized.[5] This has been noted in tertiary care institutions, such as the Shriners Hospitals for Children, which focus on the treatment of pediatric burns. It is no coincidence that more than 60% of burns in the United States are admitted to 1 of 127 hospitals with specialized burn centers.[3] These centers are staffed by experienced burn and plastic surgeons working with a cadre of anesthesiologists, burn nurses, pharmacists, respiratory therapists, occupational and physical therapists, and social

workers to produce optimal outcomes for pediatric patients. Although care in this specialized setting is not required for most pediatric burns, an understanding of burn pathophysiology and the principles of burn management will aid in the care of these patients by all clinicians.

Types of Burn Injuries

Scald Burns

Infants and toddlers younger than 5 years have a higher incidence of scald burns compared with older children.[6,7] In recent series, scald injuries accounted for the majority of pediatric burn admissions both globally and in the United States.[8-10] Accidental hot liquid spills account for many of these injuries, and a thorough history should include the type and consistency of the causative liquid. Compared with water and thin liquids, oil and thick soups have a higher heat capacity and are more viscous. This may translate into longer contact and higher temperatures causing greater skin and soft tissue damage. In general, water heated to a temperature of 60°C (140°F) will cause a deep burn after 5 seconds of contact; water heated to 68°C (155°F) will cause the same burn after 1 second of contact.[11] Scald burns are more likely to be associated with child abuse than other types of burn injuries.[12] Classic scald patterns consistent with child abuse include glovelike or stocking-like burns to the hands or feet and/or symmetric burns to the buttocks, legs, or perineum. Concomitant injuries including bruising, fractures, and retinal hemorrhages, as well as delays in seeking treatment or inconsistencies in the patient history, should trigger concern. These scenarios must prompt a full evaluation by social services with referral to appropriate state or government agencies regardless of the depth or extent of burn.

Thermal Burns

Thermal injury secondary to flame or contact with hot objects remains prevalent in pediatric burn injuries.[13] They account for approximately 50% of all burn admissions. Injuries from contact or flame are the most common cause of burn injury in children older than 5 years.[14] Up to 90% of injuries are minor and can be managed on an outpatient basis with good outcomes.[15] In larger burns, however, mortality is greatly influenced by the size of the burn, age of the patient, and presence or absence of concomitant inhalation injury.[5,15] The extent of soft tissue injury is greatly dependent on the duration of exposure and the presence and type of clothing material, all of which should be investigated during the initial evaluation.

Electrical Burns

Electrical burns remain rare, accounting for 2% to 3% of pediatric burns.[16] The majority of injuries involve electrical cords and outlets, with a rare minority from lightning. Most homes in the United States use alternating current (AC), which, although more efficient than direct current (DC), is more dangerous.[17] Injuries caused by AC have the potential for increased tissue damage from tetanic contractions caused by cyclic flow of electricity.[16] In addition, the “let go” threshold,

the maximum current a person can grasp and "let go," is lower for children than adults.[16] Children are more susceptible to electrical injuries due to their propensity to chew on cords or insert objects into outlets. Wet or moist skin, including the mucous membranes around the mouth, has negligible resistance, and these injuries often result in considerable soft tissue trauma. Nerves, blood vessels, and muscles exhibit the least resistance, as compared with bone, fat, and tendons.[16] The clinician should be aware that lack of overt skin damage may mask more significant underlying soft tissue damage.

Chemical Burns

In 2013, the National Poison Data System reported more than 2 million poison exposures. Children younger than 3 years were involved in 35.5% of exposures, and children younger than 6 years accounted for approximately half of all exposures to poison (48.0%).[18] Household cleaning substances account for one of the top five common exposures in children 5 years or younger. Alkali drain cleaners (eg, Drano) are composed of sodium hydroxide, which causes significant tissue injury from interaction with cutaneous lipids. Initial treatment of chemical burns includes copious irrigation with tepid water for more than 15 minutes. The severity of injury is determined by not only the type and concentration of the chemical but also the duration of exposure.[19] Appropriate treatment of chemical burns never involves neutralization of the acid or base as the resultant exothermic reaction worsens tissue injury. Hydrofluoric acid burns represent a distinct clinical scenario. In addition to being a corrosive agent, fluoride causes a severe, deep liquefaction necrosis.[20] Copious irrigation will attenuate the initial chemical burn, but neutralization with calcium or magnesium is occasionally necessary to halt further necrosis. Current treatment recommendations include topical calcium and close monitoring of serum calcium levels with supplementation as needed.[21]

Blast Injury

Blast injuries are a potential cause of significant thermal injury with concomitant traumatic injuries. There have been an increasing number of pediatric blast admissions secondary to methamphetamine-related explosions.[22,23] In addition to burn injuries, these children will often display the signs and symptoms of tachycardia, agitation, irritability, and emesis secondary to methamphetamine poisoning.[22] Traditionally, blast injuries are divided into four categories: primary, secondary, tertiary, and quaternary (or miscellaneous) injuries (Table 117.1). A patient may be injured by more than one of these mechanisms.[24-26]

TABLE 117.1
Classification of Blast Injuries

Type	Definition	Example
Primary	Injury from overpressurization force impacting the body surface	Tympanic membrane rupture, pulmonary damage, hollow viscus injury
Secondary	Injury from projectiles (bomb fragments, flying debris)	Penetrating trauma, fragmentation injuries, blunt trauma
Tertiary	Injuries from displacement of victim	Blunt/penetrating trauma, fractures, and traumatic amputation
Quaternary	All other injuries related to the blast	Burns, crush injury, asphyxia, toxic exposures,

		exacerbations of chronic illness

Most bomb-related burns cover less than 20% total body surface area (TBSA) and are often associated with additional injuries. The management of thermal burns secondary to blast injuries follows the same treatment plan as a burn injury.[24] The initial step is to stop the burning process, remove the clothing, wash the burn with tepid water, and then examine the extent of the burn. There should be a high index of suspicion of inhalation, blast lung, and chest injuries. Inhalation injury can result from the explosion's extinction of available oxygen and creation of particulate matter, smoke, superheated gases, and toxic byproducts.[26] Chest injuries, usually secondary to blunt force, are a common cause of death in children following an explosive blast. “Blast lung” is a direct consequence of the overpressurization wave. Signs of blast lung are usually present at the time of initial evaluation, but they have been reported as late as 48 hours after the explosion. The clinical triad of apnea, bradycardia, and hypotension characterizes blast lung injury.[26] The resuscitation of patients who sustain a thermal injury with an inhalation, blast lung, or chest injury is complicated by conflicting fluid requirements.

Depth and Extent of the Burn Injury

Normal Anatomy

The skin serves a thermoregulatory role, along with providing protection against fluid loss, mechanical damage, and infection. Divided into two distinct layers, the epidermis consists of keratinocytes, melanocytes, and Langerhans cells, all with barrier function[27] (Fig. 117.1). The dermis consists of structural proteins and cells responsible for tensile strength.[20] Additional appendages including blood vessels, hair follicles, and sweat glands are rooted in the dermis and are responsible for the regeneration of epidermal cells after superficial injury.[15] Assessment of burn depth is vital as deeper burns destroy these dermal appendages. Without skin grafting, the wounds heal from the margins of injury resulting in delayed healing, wound infection, and debilitating scars and contractures.

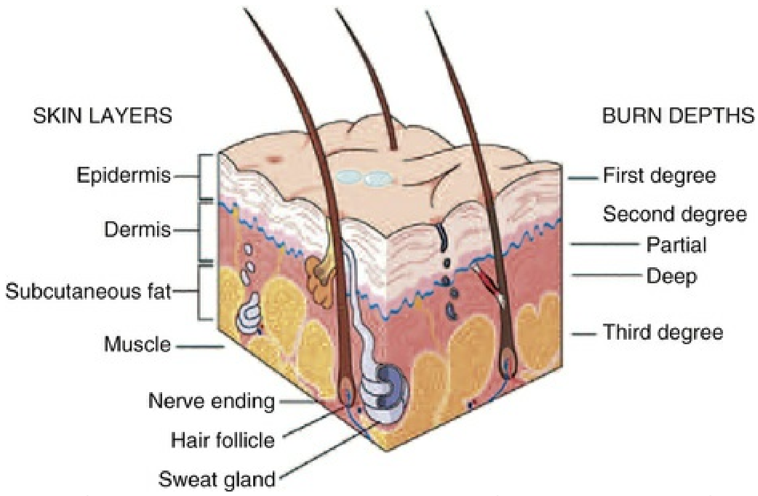

FIG. 117.1 Cross-sectional representation of normal layers of skin and subcutaneous tissue *(left)* as well as representative degrees of burn injury

based on depth of burn *(right)*. (Modified from Kagan R, Peck M, Ahrenholz D, et al. Surgical management of the burn wound and use of skin substitutes: an expert panel white paper. J Burn Care Res. 2013;34:e60-79.)

Superficial Burns

Traditionally, burn depth has been categorized as either first, second, third, or fourth degree. Although these terms are commonly used, division of burn depth and severity guided by the need for surgical treatment may be more clinically relevant. First-degree, or superficial, burns are characterized by erythematous changes, lack of blistering, and significant pain. Damage is isolated to part of the epidermis only, sparing the dermis and dermal structures. These burns blanch easily on examination and heal within 2 to 3 days after the damaged epidermis desquamates. This level of injury is exemplified by sun overexposure. Scarring is rare given the superficial depth.[15]

Superficial Partial-Thickness Burns

Superficial partial-thickness burn wounds differ from first-degree burns in that the entire epidermis and superficial dermis are injured. These burns typically form fluid-containing blisters at the dermal-epidermal junction. After debridement, the underlying dermis is erythematous, appears wet, is painful, and blanches with pressure. As the deeper dermis is left undamaged, wounds heal within 2 weeks without the need for skin grafting, typically without hypertrophic scarring, although there may be long-term pigment changes.[15]

Deep Partial-Thickness Burns

Both superficial and deep partial-thickness burns have traditionally been classified as second-degree burns. These two categories merit distinction as deep partial-thickness burns and behave clinically similar to third-degree burns. Deep partial-thickness burns blister, but as tissue damage extends deep into the dermis, the blister base may appear to have a mottled pink and white appearance. The blood vessels of the dermis are partially damaged, giving rise to variance in discoloration of the wound base. These wounds do not easily blanch and are less painful than superficial burns due to nerve injury. Treatment of these wounds customarily requires excision and grafting. Some burn surgeons advocate initial monitoring for up to 14 days to allow for demarcation. Arguments in favor of this approach cite the need for fewer operations and less extensive grafting. Rarely, these wounds will heal without surgical intervention but remain at risk for developing hypertrophic burn scars and/or contractures.[15,27]

Full-Thickness Burns

Full-thickness burns are synonymous with third-degree injuries. These wounds are defined by complete involvement of all skin layers and require definitive surgical management. On examination, these wounds are white, cherry red, brown, or black in color and do not blanch with pressure. The burned areas are dry and often

leathery compared with normal skin. Wounds are typically insensate because of superficial nerve injury. Fourth-degree burns are full-thickness injuries involving the underlying subcutaneous fat, muscle, and tendons (Fig. 117.1). These injuries are more commonly associated with limb loss and/or need for extensive reconstruction in addition to grafting.[15,27]

Zones of Injury

Burn wounds continue to evolve for days after the initial injury, and the subsequent inflammatory process may last for several months.[28] The wound is divided into zones of injury: zone of coagulation, zone of stasis, and zone of hyperemia. The zone of coagulation is easily identified, as it comprises the necrotic tissues closest to the injury site. The zone of hyperemia consists of normal, uninjured skin with a physiologic increase of blood flow in response to local tissue injury. The zone of stasis is located between the zones of coagulation and hyperemia, representing an area of ongoing injury.[20] Poor perfusion of this zone can result in the progression of initially viable tissue in this area to further necrosis and deeper wounds. Tobalem et al.[29] used an animal burn model to demonstrate that early erythropoietin administration prevented burn progression, mainly by improved vascular perfusion. Although this is not used for the treatment of pediatric burns, current research is targeting new methods to salvage these zones of intermediate injury.[30] In addition, laser Doppler imaging is currently being used to predict burn outcome on the basis of the measurement of cutaneous blood flow, targeting shorter times to excision and grafting, and subsequent decreased hospital lengths of stay.[31]

Estimating the Extent of the Burn

An accurate assessment of both the extent and depth of the burn is necessary to guide initial therapy and minimize morbidity and mortality. TBSA involvement of the burned area is an independent risk factor that correlates with length of hospital stay and mortality in pediatric burn injuries[5]; however, the extent of burn injuries may be overestimated up to 75% by the initial care provider.[32] This results in over-resuscitation with resultant devastating complications, inappropriate transfer to burn centers, and poor use of limited resources.[33] Newer methods are being researched to improve the calculation of burn surface area using computerized imaging, two- and three-dimensional graphics, and body contour reproductions.[34]

Current methods of calculating combined second- and third-degree burn size in adults include burn diagrams, the “rule of nines,” and a general estimate that the palm and fingers of one hand account for 1% of the normal body surface area.[35] Palaski and Tennison[36] developed the rule of nines, a rough estimation of adult body surface area divided into multiples of 9%. This calculation rarely underestimates TBSA but often overestimates it, especially in children.[36] Body surface area is distributed differently in children and infants due to proportionally larger heads and smaller extremities. This supports the need for age-specific surface area charts such as the Lund-Browder diagram to better estimate the extent of burn in children (Fig. 117.2).

Burn Estimate and Diagram

Early Management of Burn Injuries

Successful management of the patient with burn injury begins at the scene of injury and continues in the emergency department with a thorough Advanced Trauma Life Support (ATLS) trauma assessment, as well as the American Burn Association's Advanced Burn Life Support (ABLS) assessment.[37,38] Patients must be removed from the thermal source of injury, and burns should be washed with tepid water.[38,39] Chemical burns from liquid chemicals should be flushed copiously to remove the inciting agent and prevent further tissue damage. Dry chemicals should be brushed off before any irrigation. Ice or iced water has been shown in animal studies to increase tissue damage and mortality and should not be used given the added risk of hypothermia in patients with more extensive burns.[40,41] Approximately 10% of all burn patients present with additional traumatic injuries, and the primary caregiver

should not be distracted by obvious external burn injury when performing a rapid trauma evaluation.[15] Patients with severe burn shock or trauma are at risk for loss of airway due to altered mental status or supraglottic obstruction from edema formation.[42] Signs of potential inhalation injury include facial burns, singed nasal hairs, carbonaceous sputum, hypoxia, and history of entrapment in an enclosed space. Individually, these symptoms carry a high false-positive rate for inhalation injury but merit temporary treatment with supplemental oxygen until a definitive diagnosis is made. Initiation of resuscitation is reserved for infants and children with 10% or greater TBSA burns, teenagers with 15% or greater TBSA burns, and industrial and high-voltage electrical burns. Electrical injuries require specific evaluation given the propensity for compartment syndromes and multiorgan system involvement. Cardiac dysrhythmias and direct muscle necrosis can develop with high-voltage electrical burns, requiring intervention or prolonged cardiac monitoring.[16] Seizures and spinal cord transections are possible, as well as respiratory arrest secondary to injury of the brain stem or tetany of the respiratory musculature.[16]

After a complete primary and secondary survey, attention should turn to evaluation and management of the burn injury. Using appropriate tools such as the Lund-Browder chart, the depth and extent of burn should be assessed and used to guide further care. Approximately 60% to 70% of burns seen in emergency departments involve less than 10% TBSA.[14] The majority of these burns can be treated safely with minor debridement, oral hydration, topical wound care, and outpatient follow-up. Those patients requiring supplemental nutrition or hydration, or who fail outpatient treatment, may need continued care in an inpatient setting. In adults with more than 20% TBSA involvement, in infants with more than 10% TBSA involvement, or if there is a suspicion for inhalation injury, inpatient treatment with IV resuscitation and potential transfer to a burn center should be considered.

Transfer to Burn Centers

The optimal treatment and management of large or complicated burn injuries are in a high-volume center by a multidisciplinary team including burn surgeons and nurses, physical and occupational therapists, dietitians, psychiatrists, respiratory therapists, and social service support staff.[43] Current American Burn Association guidelines recommend the transfer of patients with severe injuries or those meetings specific criteria to dedicated burn centers (Table 117.2). Before transfer, airway assessment and protection, initiation of resuscitation, and evaluation for coexisting injuries should be performed.[37] Inhalation injury may go unrecognized at the initial assessment. The presence of airway injury, signs of airway obstruction, and the presence of preexisting airway abnormality should be assessed as soon as the patient arrives at the hospital.[37] Subsequently the burn wounds should be covered with clean, dry material or nonadherent gauze.[44] The use of wet dressings should be avoided to prevent development of hypothermia and subsequent complications in patients with large burn wounds.[43] Tetanus prophylaxis should be administered along with appropriate pain control before transport. In patients with extensive burns, a Foley catheter should be inserted to help guide fluid management.

TABLE 117.2

American Burn Association Criteria for Burn Center Referral

• Partial- and full-thickness burns >10% TBSA in patients <10 years or >50 years
• Partial- and full-thickness burns >20% TBSA in patients in other age groups
• Partial- and full-thickness burns involving face, hands, feet, genitalia, perineum, or major joints
• Electrical burns
• Chemical burns
• Inhalation injury
• Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or increase mortality rate
• Any burn with concomitant trauma in which the burn injury poses the greatest risk
• Burn injury in children admitted to hospitals without qualified personnel or equipment for pediatric care
• Burn injury in patients requiring special social, emotional, or rehabilitative support, including child abuse cases

TBSA, total body surface area.

Burn Resuscitation

The first 48 hours of treating pediatric burn patients are the most critical due to the burn-induced hypovolemic shock these patients exhibit.[38] In children with more than 10% TBSA involvement, adequate IV access should be obtained via peripheral or central routes. Delayed initiation of resuscitation has been shown to increase mortality following severe burn injury in children.[5] Infusion of a balanced crystalloid solution should be started as soon as IV access is obtained, with the infusion rate titrated after full assessment of burn injury. Initial resuscitation guidelines have historically followed one of two formulas, the Parkland or modified Brooke. These formulas serve only as guidelines. Resuscitation must be tailored to each individual patient with the goal of restoring and maintaining perfusion without inducing fluid overload.

The Parkland formula was developed in the 1970s by Baxter and Shires, arising out of 30% to 50% TBSA flame burn experiments in dogs. They found that resuscitating with a higher volume in the first 8 hours improved cardiac output, which could be maintained over the next 16 hours with lower fluid rates. On the basis of these studies, recommendations for resuscitation of large burns using the Parkland formula were extrapolated.[45] This formula recommends the total administration of 4 mL/kg/%TBSA burn over the first 24 hours post injury. One-half of this volume is administered during the first 8 hours with the remaining volume delivered during the next 16 hours.

Although the Parkland formula is the most widely used resuscitation formula, it is closely followed by the modified Brooke formula. On the basis of the work done at the Brooke Army Burn Center, Pruitt et al. altered the original Brooke formula, which recommended 1.5 mL/kg/%TBSA burn of crystalloid and 0.5 mL/kg/%TBSA burn of colloid. This group demonstrated that a lower volume of fluid could achieve the same endpoints of resuscitation as the Parkland formula.[45] The modified Brooke formula calls for 2 mL/kg/%TBSA burn of balanced salt solution over the first 24 hours after injury and no colloids. Although both formulas call for the titration of fluid rates, in a comparative analysis, the Parkland formula more often resulted in over-resuscitation, proving to be an independent risk factor for mortality.[46] A separate comparative study found no clinical differences in outcomes between patients resuscitated using these two formulas.[47]

Consensus fluid resuscitation by standardized formula has not been reached.[45] In children, resuscitation strategies should include the administration of estimated

basal fluid requirements in addition to the replacement of extensive fluid losses secondary to burn injury. Pruitt first used the term "fluid creep" to describe the insidious increase in the volume of fluid that burn centers administer in the first 24 to 48 post burn in a well-meaning effort to avoid the onset of early acute renal failure.[48] At our institution the child's basal fluid requirements (1500 mL/m^2 body surface area or 2000 mL/m^2 body surface area for children younger than 2 years) are added to the resuscitation calculated using the Parkland formula (Table 117.3). All formulas rely on the accurate assessment of extent and depth of burn in order to provide appropriate resuscitation. Fluid requirements should be titrated for clinical endpoints including urine output of 0.5 to 1 mL/kg/hr in children[46] and restoration of appropriate hemodynamic parameters.[45] Swords et al. demonstrated that nearly 20% of children arrived at the burn center without a TBSA estimation and 50% of burns were overestimated by at least 5%.[49] To avoid the complications of inadequate or excessive resuscitation, current research is being performed to examine the utility and efficacy of non-invasive computational algorithms,[50,51] as well as an invasive transcardiopulmonary thermodilution monitoring device (Pulse index Continuous Cardiac Output [PiCCO] device) to guide resuscitation.[52]

TABLE 117.3

Shriners Hospital for Children–Cincinnati Resuscitation Worksheet

RESUSCITATION CALCULATIONS
I. RESUSCITATION
A. Calculated resuscitation and basal requirement
(4 mL × ______ kg × ______%TBSA) + (*1500 mL × ______m^2) =______ mL/24 hours
(________ + ________) = ________mL/24 hours
B. Resuscitation fluid per 8 hours
1st 8 hours ________mL, ________mL/hour
2nd 8 hours ________mL, ________mL/hour
3rd 8 hours ________mL, ________mL/hour
II. MAINTENANCE FLUIDS
A. Basal fluid requirement
*1500 mL × ________m^2 = ________mL/hour
B. Evaporative water loss
If child ≥20 kg – (25 + %TBSA) m^2 = mL/hour
If child <20 kg – (35 + %TBSA) m^2 = mL/hour
(______ + ______ %TBSA) ______m^2 = ______mL/hour
C. Total maintenance fluid = basal fluid requirement + evaporative water loss
(________ + ________) = ________mL/hour

*1500 mL if child >2 years old; 2000 mL if child ≤2 years old.

Colloid Resuscitation

The timing and use of colloid in burn resuscitation are controversial. Historically, initial resuscitation formulas called for its use in the first 24 hours after injury as an adjunct to crystalloid.[45] In pediatric patients with extensive burn injury, colloid replacement is sometimes necessary due to rapid serum protein depletion resulting in crystalloid resuscitation failure. Lawrence et al.[54] described the addition of colloid to resuscitation of severely burned patients, which rapidly eventually reduced the hourly fluid requirements, restored normal resuscitation ratios, and ameliorated fluid creep. However, previous evidence has shown that colloid resuscitation provides no long-term benefits, does not affect mortality, and is more expensive compared with crystalloid solutions.[55] The theoretic reduction in complications and

mortality with colloid use has not been demonstrated in human trials.

Complications of Resuscitation

Inadequate resuscitation may result in poor perfusion to both vital organs and the evolving zone of stasis. This leads to necrosis of previously viable tissue and progression of superficial burns to deeper injuries requiring grafting.[30] The complications of fluid overload in burned patients are associated with pneumonia, bloodstream infections, acute respiratory distress syndrome (ARDS), acute respiratory failure, multiple organ failure, extremity compartment syndrome, abdominal compartment syndrome, and death.[56-60] The volume infused should be continuously titrated to avoid both over-resuscitation and under-resuscitation with little to no role for fluid bolus therapy during initial burn management.[53]

Risks for the development of compartment syndrome in the extremities, torso, or abdomen have been linked to the presence of deep, full-thickness circumferential burns, as well as the volume of fluid infused during resuscitation. Severe burn injury results in a systemic inflammatory response leading to microcirculatory leak, vasodilatation, and decreased cardiac output and contractility.[61] With tissue edema, reperfusion injury following resuscitation, and external compression from circumferential burns, compartment syndromes may develop, most commonly within the first 24 to 48 hours. Excessive fluid resuscitation increases the incidence of compartment syndrome and leads to additional complications.[59] Clinical suspicion of compartment syndrome is supported by findings of delayed capillary refill, cyanosis, paresthesia, and diminished pulses. It is imperative to make the diagnosis before the loss of pulses as this indicates long-standing compartment syndrome with a higher likelihood of muscle necrosis and nerve damage. Compartment pressures can be measured using the Intra-Compartmental Pressure Monitor (Stryker Orthopaedics, Mahwah, New Jersey, USA) or an 18-gauge needle inserted under the eschar into the subcutaneous or subfascial layer and connected to an arterial pressure transducer.[62] A pressure greater than 30 mm Hg is considered diagnostic, mandating decompression through escharotomy and/or fasciotomy. Escharotomies are performed at the bedside under sedation with electrocautery used to incise the full length of eschar down to subcutaneous fat along defined lines of incision (Fig. 117.3). Bulging of surrounding tissues demonstrates adequate decompression. Fasciotomies are generally performed in the operating room under general anesthesia. All extremity compartments must be opened with evaluation of muscle for signs of necrosis. Escharotomies and fasciotomies should only be performed by experienced practitioners due to increased morbidity from incorrectly executed procedures.[63]

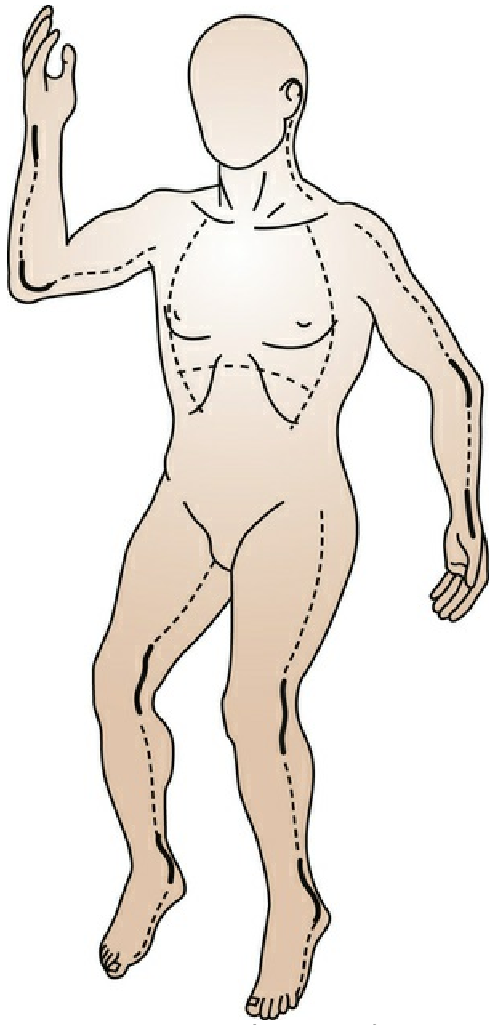

FIG. 117.3 Recommended lines of incision for escharotomies of the extremities and torso.

Abdominal hypertension with subsequent compartment syndrome significantly decreases perfusion to vital organs including the small and large bowel, liver, and kidneys, thereby contributing to the development of multisystem organ failure.[45] Patients will often present clinically with abdominal distention and decreased urine output. In addition, decreased pulmonary compliance secondary to elevated abdominal pressures can compound respiratory challenges. The incidence of intraabdominal hypertension in patients with extensive burns is approximately 70%, with up to 20% of those identified requiring decompressive laparotomy.[61] Preventive measures to avoid abdominal compartment syndrome include appropriate titration of resuscitation fluid, as well as early recognition of abdominal hypertension through serial bladder pressure evaluations.[64] Timely decompressive laparotomy should be performed at the onset of increased compartment pressures to avoid significantly increased morbidity and mortality related to fluid loss with an open abdomen. In small children, percutaneous drainage using peritoneal dialysis catheters may be an effective alternative to laparotomy provided that the increased intraabdominal pressure is related to fluid accumulation and not organ edema. Latenser et al.[65] in a pilot study compared percutaneous drainage with surgical decompressive laparotomy in adult and pediatric patients with greater than 40% TBSA burns. They concluded that percutaneous drainage is safe and effective as a

decompression modality for decreasing intraabdominal hypertension and preventing acute compartment syndrome in patients with less than 80% TBSA burns.[66] The development of pulmonary complications including acute lung injury (ALI), pulmonary edema, and ARDS has been attributed to excessive fluid resuscitation.[67] In the absence of inhalation injury, the systemic inflammation seen after severe burn injury results in third spacing of fluids and accumulation of interstitial edema in the lungs. The treatment of this immune response remains challenging. Alternative resuscitation strategies including the use of colloid and hypertonic saline as adjuncts to crystalloids are continually being investigated with mixed results.[67,68] Sun et al.[69] discovered, with the use of a burn model in rats, that initial resuscitation with hypertonic saline after severe burn injury decreases pulmonary edema, prevents hyponatremia, and attenuates oxidative stress but is not capable of inhibiting the systemic inflammatory response. In several series, the presence of inhalation injury results in increased resuscitation fluid requirements and is predictive of the development of respiratory failure and increased mortality.[5,15,55,70]

Inhalational Injury

The diagnosis of inhalation injury in burn patients is important as there is a clear link that exists between inhalation injury and mortality.[71] The presence of inhalation injury is the single most important risk factor for mortality, and inhalation injury is implicated in approximately 50% of all burn-related mortalities. In age-specific studies of mortality, the presence of concomitant inhalational injury increased mortality across all ages, but its effect on mortality was largest in the pediatric burn patient population.[72]

Pathophysiology of Inhalation Injury

Inhalation injury involves exposure of the upper airway to heated dry air or steam. The lower airway, consisting of the tracheobronchial tree and lung parenchyma, is rarely injured by the heated dry air because of reflexive vocal cord closure and evaporative cooling capacity, in addition to other natural defense mechanisms.[11,73] Direct thermal injury of the upper airway, however, manifests with significant inflammation and edema. Histamine release, signaled by increasing complement at the site of injury, produces reactive oxygen and nitrogen species. These reactive species increase vascular permeability leading to extrusion of fluid and increased tissue edema, which propagates pulmonary injury. Prolonged extrusion of proteinaceous exudate and associated tissue edema may result in the formation of airway casts and upper airway obstruction, similar to mucous plugging.[42,74]

Smoke and inhaled toxins pose a particular risk to both upper and lower airways. While large inhaled particles are filtered by the upper airway, both small particles (<5–10 μm) and noxious gases can reach the lower airway and cause injury.[75] Toxins such as ammonia, sulfur oxides, pyrolysates, and chlorine gas form strong alkalis and acids upon contact with the moist, mucosal walls of the upper and lower airways.[76] Fat-soluble agents, such as aromatics, activate alveolar macrophages and may initiate direct cellular damage resulting in hyperemia, which can be visible by bronchoscopy shortly after injury.[77] While water-soluble irritants cause

instantaneous pain, fat-soluble agents tend to be less noxious agents and reach the distal airways more easily, bypassing natural defense mechanisms. If these inhalants induce an inflammatory response in the pulmonary parenchyma, surfactant synthesis may be disrupted with further worsening of lung compliance.[75,78] Loss of ciliary action in the respiratory mucosa can lead to increased pulmonary infections, ultimately resulting in irreparable damage to the respiratory tree.[42]

Carbon monoxide (CO) and cyanide are key components of inhalation injury in the acute burn patient, and each poses diagnostic challenges. CO is an odorless, colorless gas generated by incomplete combustion of carbon-containing materials.[75] In CO poisoning, tissue oxygenation is impaired, resulting in a range of symptoms including headache, nausea, irritability in mild intoxication, tachypnea, hypoxia, altered mental status, coma, and ultimately death.[79] These clinical signs stem from an increased affinity of CO to bind hemoglobin, resulting in carboxyhemoglobin (COHb) formation, as well as a left shift of the oxygen-hemoglobin dissociation curve, interfering with normal unloading of oxygen to tissues. Relative tissue hypoxia ensues with subsequent metabolic acidosis.[75] Hydrogen cyanide, a colorless gas with an odor described as being similar to bitter almonds, is produced by combustion of carbon and nitrogen-containing substances (ie, wool, cotton). Cyanide inhibits oxidative phosphorylation via reversible inhibition of cytochrome c oxidase. Similar to CO poisoning, cyanide poisoning produces relative tissue anoxia and metabolic acidosis.[80]

Diagnosis of Inhalation Injury

The diagnosis of inhalation injury begins with a focused history and physical examination. The mechanism of injury provides a strong indication of risk in the pediatric burn patient. Closed-space burns involving steam, combustibles, hot gases, or explosions should alert the treating physician to possible airway injury. Clinicians should be cognizant that inhalation injury may occur without evidence of cutaneous burns. The physical examination should include inspection for soot in the oropharynx, carbonaceous sputum, singed nasal or facial hairs, and burns involving the face or neck. These signs taken individually have a high false positive in the diagnosis of inhalational injury but should raise clinical suspicion.[42] Impending respiratory distress may manifest as wheezing, stridor, tachypnea or hoarseness, along with depressed mental status, agitation, or anxiety. Many pediatric patients with inhalation injury will develop progressive respiratory failure, tachypnea, hypoxia, and cyanosis after resuscitation, even when appearing normal upon initial presentation.

In addition to the nonspecific clinical signs and symptoms of inhalational injury, noninvasive monitoring of pulse oximetry in burn patients can be misleading. For this reason, laboratory and invasive studies are pertinent to diagnosis. Initial laboratory studies should include arterial blood gas (ABG) analysis and measurement of carboxyhemoglobin (COHb). The partial pressure of oxygen in arterial blood to the fraction of inspired oxygen (PaO_2/FiO_2) ratio of less than 300 is indicative of significant inhalation injury, with early evidence of ALI.[81] Albeit controversial, this ratio has been proposed as an indicator of poor outcome in burn patients.[82,83] For suspected CO poisoning, COHb values should be drawn and correlated with time from injury. At sea level, when breathing room air, the half-life

of CO is 240 to 320 minutes, decreasing to 30 to 40 minutes when breathing 100% oxygen.[84] The half-life of CO falls to 20 minutes when exposed to hyperbaric oxygen conditions; however, there is little evidence for the use of hyperbaric oxygen for treatment of CO poisoning. Given the potential risks of hyperbaric oxygen including barotrauma and inability to access critically ill patients, treatment of CO poisoning with hyperbaric oxygen is not recommended. If cyanide poisoning is suspected, blood cyanide levels should be also drawn with prompt administration of antidotes.[80]

Chest radiographs and computed tomography scans are insensitive for the diagnosis due to a relatively normal lung and airway appearance early in the clinical course.[85,86] Repeat studies over time and after resuscitation may demonstrate subsequent development of pulmonary edema or ARDS. Historically, Xenon-133 scanning has been used to evaluate parenchymal injury, demonstrating trapping or delayed excretion of the radioactive isotope within injured lungs.[87] This technique is limited by its availability and technical expertise, and it is rarely used.[81] Fiberoptic bronchoscopy remains the gold standard for the diagnosis of inhalation injury. Direct visualization of the supraglottic and infraglottic airway allows quantification of hyperemia, exudate, mucosal sloughing, edema, and presence of carbonaceous material. In a study spanning a 10-year period, 71% of pediatric patients with inhalation injury were diagnosed using bronchoscopy versus 25% by history/clinical examination alone and 4% by carboxyhemoglobin levels, demonstrating that even at specialized burn centers, there remains variability in means for diagnosing inhalation injury.[71]

Management of Inhalation Injury

Inhalation injuries can quickly progress to obstruction, hypoxia, and death, so timely endotracheal intubation is required. If inhalation injury is suspected in a pediatric patient, prompt endotracheal intubation is necessary due to the small size of the airway, leading to an increased likelihood of adverse events due to early obstruction. Oxygen therapy at a FiO_2 of 1.0 should be initiated immediately to treat increased COHb levels and provide maximal oxygen delivery to peripheral tissues.[75] Duration of oxygen therapy depends on patient condition and can be quantified by documenting return of carboxyhemoglobin levels to below 10% and normalization of acidosis.[88] Continuous pulse oximetry may be reliably used after normalization of COHb levels. Inhalational injuries rapidly evolve over the first few days following injury. Acute pulmonary insufficiency may manifest in the first 24 hours, with edema peaking between 48 and 96 hours, and injury culminating in bronchopneumonia 3 to 10 days post burn. The treatment of inhalational injuries needs to be tailored accordingly and is mainly supportive, consisting of ventilator support, airway clearance, and therapeutic adjuncts.

Ventilator Support

Following endotracheal intubation, the acute burn patient with inhalation injury may benefit from alternative modes of ventilation as compared with conventional strategies. The choice of mode is dictated by patient condition, clinician and staff familiarity, and treatments required (ie, repeat bronchoscopy, inhalation agents), and when used appropriately, standard ventilator strategies may provide adequate

support. In severe inhalational injury the use of high-frequency oscillatory ventilation may be beneficial, and single centers have shown early and sustained improvement in oxygenation with its use.[89] However, use of high-frequency oscillatory ventilation may limit delivery of important inhaled medications and timely serial bronchoscopy, which are important adjuncts in the treatment of inhalational injury. Volumetric diffusive respiratory (VDR) mode provides ventilation and oxygenation with a decreased mean airway pressure, reducing the risk of barotrauma (Fig. 117.4). VDR mode involves high-frequency ventilation with progressive accumulation of subtidal breaths and passive exhalation once a set airway pressure is met, allowing for gas exchange through more recruited alveoli.[90,91] In a small prospective study of pediatric burn patients, Rodeberg et al.[90,92] demonstrated that use of VDR mode increased PaO_2, increased PaO_2/FIO_2 ratio, and decreased mean airway pressure, all without affecting hemodynamic function. Long term, this mode has been shown to decrease pneumonia and mortality compared with individuals treated with conventional modes of ventilation, but data remain limited in pediatric burn patients.[91,93-95] Airway pressure release ventilation (APRV) is a reverse inspiratory/expiratory method of ventilation with two levels of PEEP support (Fig. 117.5). High PEEP is continuous during a prolonged inspiratory time, providing for adequate oxygenation and recruitment of closed alveoli, while low PEEP is maintained during expiration facilitating recruitment of alveoli. Theoretically, patients benefit from reduced barotrauma, improved oxygenation and ventilation due to better V/Q matching, and decreased sedation and paralysis requirements due to increased patient comfort.[96] Unlike the VDR, there is no percussive component involved.[97] Data remain limited regarding use of both these alternative ventilatory strategies in the pediatric burn setting and are extrapolated from adult literature.

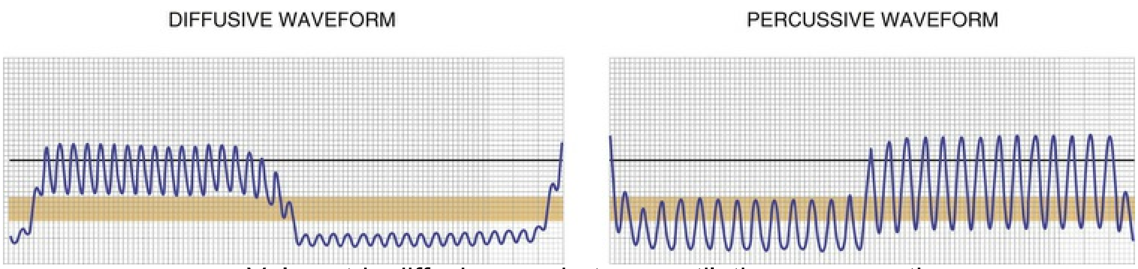

FIG. 117.4 Volumetric diffusive respiratory ventilation pressure-time tracings. Percussive and diffusive waveforms from a pediatric burn patient volumetric diffusive respiratory ventilator at Shriners Hospital for Children–Cincinnati.

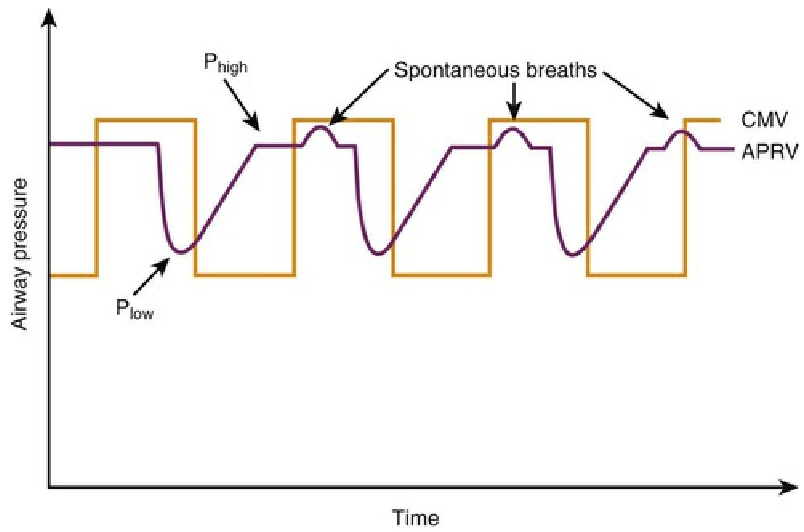

FIG. 117.5 Airway pressure release ventilation and controlled mechanical ventilation pressure-time tracing. (Modified from Fan E, Stewart TE. New modalities of mechanical ventilation: high frequency oscillatory ventilation and airway pressure release ventilation. Clin Chest Med. 2006;27:615-625.)

Airway Clearance

Appropriately trained respiratory therapists are invaluable in the management of burn patients and are a mainstay in specialized burn care units. Together with ventilatory management, other adjunctive therapies including aggressive pulmonary toilet and chest physiotherapy are essential components of treatment of inhalational injuries. Chest percussion and vibrational treatment with additional focus on early ambulation are effective strategies for secretion mobilization and removal. Tracheobronchial suctioning and serial therapeutic bronchoscopies are often necessary to maintain airway clearance in severe inhalational injuries and are vital to prevent postobstructive atelectasis and infectious complications stemming from the excess mucus and fibrin casts characteristic of inhalational injury.[42,98,99]

Therapeutic Adjuncts

To combat the bronchoconstriction and excess secretions encountered in inhalational injuries, bronchodilators and pharmacologic treatments including nitric oxide, nebulized heparin, and *N*-acetylcysteine may be used. β-Adrenergic agonists are widely used in treatment of lung conditions including asthma and ARDS/ALI. The aerosolized delivery of specific β_2-adrenergic agonists produces preferential effects including bronchodilation, attenuation of lung inflammation, and potentially increased fluid clearance with limited systemic cardiac activation.[100] One retrospective review of burn children showed increased PaO_2/FIO_2 ratios and improved compliance and pH during treatment with continuous albuterol therapy.[100] Inhaled nitric oxide is a short-acting vasodilator used in the treatment of pulmonary hypertension that works by increasing cyclic guanine monophosphate in smooth muscle.[101] Limited studies in burn patients have demonstrated variable improvement in PaO_2/FIO_2 ratios and improved survival in those patients who respond to treatment.[102] If a response is not demonstrated between doses of 5 and 20

ppm of nitric oxide within 60 minutes of treatment onset, the patient is unlikely to respond and therapy should be discontinued due to futility and cost.[102] Nebulized heparin and tissue plasminogen activation have demonstrated potential efficacy in both animal and adult human studies through breakdown of fibrin deposition with maintenance of alveolar structure and reduced airway obstruction.[99,103] The mechanisms by which aerosolized heparin exerts a beneficial effect in inhalation injury are as yet undetermined but may be related to breakdown of fibrin casts and reduction in the inflammatory response from neutrophil migration into the airways.[99] Multicenter randomized trials are currently under way to delineate the beneficial effects of nebulized heparin but remain restricted to the adult burn population.[104,105] *N*-acetylcysteine, an effective mucolytic, was noted to reduce pulmonary inflammation in animal studies, demonstrating a decrease in leukocytes in bronchoalveolar lavage following a rat burn model, supporting the conclusion that *N*-acetylcysteine may ameliorate tissue damage after inhalation injury.[106] Although survival benefit has not clearly been demonstrated with use in ARDS and ALI,[107] preliminary evidence exists supporting improved outcomes when lung inflammation is attenuated, supporting research into future pharmacologic adjuncts targeting antioxidants and leukotriene inhibitors, as well as exogenous surfactant.[108] Well-designed clinical trials are necessary to further elucidate those adjunctive therapies most likely to improve morbidity and mortality in pediatric inhalation injury patients.

Perhaps most controversial in the management of inhalation injury is the use of corticosteroids. Although clearly beneficial for many chronic pulmonary diseases including asthma, benefits in acute pulmonary inflammation related to inhalation injury and ARDS have not been definitively demonstrated.[109,110] Corticosteroid therapy has been shown to increase mortality (from 13%–53%) and complication rates (from 31%–82%) in at least one study.[88] However, more recently Meduri et al.[111] demonstrated the potential utility of methylprednisolone given for 28 total days with fewer days on ventilator, a shorter ICU stay, fewer infections, and increased survival in patients with ARDS. Until larger prospective studies are completed, empiric treatment with corticosteroids for inhalation injury is not recommended.

Extracorporeal membrane oxygenation (ECMO) may be a lifesaving treatment modality in pediatric burn patients with acute respiratory failure refractory to the above standard treatments. Venoarterial (VA) ECMO when cardiopulmonary support is necessary and venovenous (VV) ECMO when the primary issue is pulmonary are both used in non–burn-related pediatric acute respiratory failure, with survival rates of 47%.[112,113] Although most documented success consists of case reports in the pediatric burn literature, Askegard-Giesman Jr. et al. queried the Extracorporeal Life Support Organization registry for the largest reported series of pediatric burn patients on ECMO. They identified 36 patients placed on either VA or VV ECMO following burn-related acute respiratory failure with documented survival rates of 53%, on par with rates reported for non–burn-related pulmonary disease.[114] This supports the feasibility of ECMO in inhalational injury; however, the treatment strategy itself is fraught with excessive morbidity, as 44% of patients suffered complications related specifically to ECMO and medical complications occurred in the majority of patients (78%).[114] While there is no consensus on criteria for initiation of ECMO therapy and its widespread technical limitations preclude widespread use of this strategy, it remains an option for clinicians as rescue therapy

for severe inhalational injuries.

Nutritional Support in Burn Patients

Nutritional support of the pediatric burn patient is paramount for prevention of malnutrition and adequate wound healing. Burns induce a hypermetabolic state that may persist for up to 12 months after injury, which contributes to underestimation of the nutritional needs of these patients.[115,116] It is commonly assumed that hypermetabolism is directly related to burn size, but more than likely it is related to stress hormones and gender, as well as age differences that must be considered.[117,118] Although exact mechanisms behind this hypermetabolism remain unclear, catecholamines including epinephrine and norepinephrine are increased following large burns. This hypermetabolic state is also thought to be secondary to inflammatory cytokines that stimulate the hypothalamus with resultant increases in the body's temperature set point, changes that are further compounded by the increased evaporative heat loss caused by the burn itself.[117] This systemic response to burn results in increased oxygen consumption, increased protein catabolism, increased lipolysis, and impaired glucose metabolism. These derangements culminate in decreased lean body mass, poor wound healing, and weakened host defenses if appropriate nutrition is not maintained.

Calculating and Monitoring Nutritional Requirements

Numerous equations have been developed to estimate the energy requirements of pediatric burn patients, although no single standard currently exists as most formulas overestimate caloric requirements.[119-122] Indirect calorimetry remains the gold standard to adjust nutritional support.[81,122] At our institution, we use the Mayes equation to calculate initial nutritional requirements, taking age, weight, and %TBSA burn into account (Table 117.4). Indirect calorimetry can then be used to calculate resting energy expenditure (REE) by measuring the differences in oxygen and carbon dioxide concentrations in inspired and expired gas and used to adjust caloric needs as appropriate. Total caloric requirements can be estimated as 120% to 130% of REE.[81] In children, carbohydrates should account for 60% to 70% of energy requirements while fats should account for 15% to 20%. Protein requirements vary from 2.5 to 4 g/kg/day.

TABLE 117.4

Mayes Equation to Calculate Energy Requirement After Burn Injury

Mayes equation for 5- to 10-year-old burn patient with <50% total body surface area (TBSA)
818 + 37.4 (weight in kilograms) + 9.3 (%TBSA burn)
Example: 5.5-year-old patient with 45% TBSA burn weighing 20 kg
818 + 37.4 (20 kg) + 9.3 (45% TBSA) 818 + 748 + 481.5 = 2047.5 calories/day

In addition to indirect calorimetry, blood tests can serve as adjuncts to aid in monitoring nutritional status.[121] While albumin is a poor surrogate for nutritional status, prealbumin is advocated as it is a distinct marker for protein synthesis and has a relative short half-life, increasing its sensitivity as a marker for nutritional support. As albumin levels rapidly fall following large burn injuries, it is unreliable as a measure of nutritional stores. In addition, albumin replacement maintains no scientific basis as it does not stimulate production of endogenous albumin, nor has replacement been shown to have any clinical benefits regarding pulmonary function, wound healing, gastrointestinal function, or mortality.[117] Static measurements of serum concentrations of nutritional markers such as carotene, iron, and calcium remain unreliable indicators of nutritional status in burn patients.[123]

Although underfeeding contributes to poor clinical outcomes, the implications of overfeeding critically ill burn patients may be just as detrimental. Excessive carbohydrate consumption leads to respiratory abnormalities that may interfere with pulmonary function and subsequent weaning from mechanical ventilation.[124] Overfeeding carbohydrates also contributes to hepatic dysfunction, hyperglycemia, dehydration via osmotic diuresis, and poor wound healing.[117,124] Although burns cause significant protein catabolism, oversupplementing with excessive quantities of protein does not help offset catabolism but may actually increase breakdown and is detrimental. Excessive lipid intake can increase susceptibility to infectious complications and cause diarrhea and fatty liver. Whereas overfeeding is a concern in the care of burned patients, the majority of literature supports early and aggressive nutritional support to prevent complications from poor wound healing and infection-related morbidity and mortality.[124,125]

Enteral Support

Enteral feeding is the mainstay of nutritional support in pediatric burn patients and is considered the ideal route for caloric and nutrient supplementation. Studies have shown enteral support helps maintain intestinal integrity following burn injury, decreasing the risk of bacterial translocation and infectious complications.[126-128] The role of specialty amino acids, proteins, and fatty acids present in commercial tube feed preparations for pediatric burn patients is controversial, as studies have both shown improvement[127] and no effect on clinical outcomes[129] and may be cost prohibitive. For burns greater than 20% TBSA, oral nutrition is often inadequate to meet the nutritional demands of the hypermetabolic state, and nasoenteric feeding tubes should be placed with initiation of supplemental tube feeding.[128] Early enteral feeding is recommended as soon as initial resuscitation is complete, as recommended by American Burn Association guidelines.

Parenteral Support

Parenteral nutrition (PN) is considered a mainstay of therapy for many critically ill patients who are not candidates for enteral nutrition. In burn patients, central venous PN is reserved for individuals unable to tolerate enteral feedings as an alternative to starvation. Complication rates increase when burn patients are given PN due to bacteremia and increased susceptibility to pneumonia. PN may be necessary in pediatric burn patients with concomitant abdominal surgery, functional

ileus, or hemodynamic instability, but all efforts should be made to initiate enteral nutrition as soon as practical.[130] Peripheral parenteral nutrition (PPN) is not recommended due to lack of adequate calorie delivery and high risk of peripheral access damage from PPN extravasation.

Nutritional Adjuncts

Although vitamin supplementation is poorly understood in children and little evidence exists in pediatric burn patients, guidelines regarding vitamin supplementation from the National Advisory Group/American Medical Association are customarily followed. Vitamin A has been shown to improve wound healing following burn injury, and vitamin D is vital for adequate bone formation in children.[131] Vitamin C plays a vital role in collagen synthesis and wound healing, necessitating its supplementation. Wound exudates were found to be the primary site of loss for trace elements, suggesting burn patients may require replacement of trace elements more than other critically ill patients.[132] The trace element zinc is involved with wound healing, and some reports suggest decreased zinc levels in septic patients are associated with subsequent adverse events.[81] For these reasons, zinc supplementation is often included as part of enteral nutrition.

Insulin resistance and hyperglycemia are known effects of the hypermetabolic response seen following burn injury. Hyperglycemia occurs in most burn patients regardless of injury severity because of increased rate of glucose production and impaired tissue glucose extraction.[133,134] Insulin may serve dual functions in burn patients, both in its anabolic effects and ability to counter hyperglycemia. Jeschke et al.[135] demonstrated tempering of the inflammatory response with tight glucose control using insulin through mediation of hepatocyte apoptosis, which allows for improved hepatic function. Tight glucose control with intensive insulin therapy has been shown to reduce postburn morbidity in a single-center prospective trial, with reductions in inflammatory response, infection, and organ dysfunction.[136] The hypercatabolism in burns leads to loss of lean body mass even with adequate nutritional support. Negative nitrogen balance is often seen during the first 1 to 2 weeks after burn.[121] To combat this, studies have demonstrated both the short- and long-term effectiveness of anabolic agents such as oxandrolone in restoration of lost lean body mass and improved wound healing.[137] These results are controversial and current literature is limited to single-center studies with regards to impact on the course of burn disease. Anabolic steroids such as oxandrolone are not universally used in the management of pediatric burn patients.

Wound Care

Burn wounds will evolve over time on the basis of factors including mechanism of injury and fluid resuscitation, sometimes requiring 10 to 14 days for complete demarcation.[27] It is not uncommon for previously diagnosed superficial partial burn wounds to demarcate as full-thickness burns and vice versa. If the burn wound is improperly managed and allowed to desiccate or become infected, it will convert to a deeper wound requiring definitive surgical management. Initial cleansing and debridement of the wound are absolutely essential for proper diagnosis of size and depth. Mild soap and water or chlorhexidine mixed in saline washes is

recommended for cleaning, with adequate pain control to allow complete debridement of necrotic tissue. Most burn experts recommend debridement of all blisters unless smaller than 0.5 cm or in a difficult-to-manage area to reduce the risk of bacterial colonization or infection.

Burn wounds become colonized in the first few hours with gram-positive bacteria such as *Staphylococcus aureus* and *epidermidis* and are predominantly colonized with gut flora such as *Pseudomonas aeruginosa, Enterobacter cloacae,* and *Escherichia coli* by 5 days.[138] Health care workers involved with the cleansing and debridement of burn wounds must be vigilant in hand washing and maintenance of a clean environment around the wound for prevention of cross-contamination in these immunocompromised patients. Culture swabs of all wound beds should be obtained on arrival and on a scheduled basis to monitor for changes in colonization. Bacterial colonization of burn wounds does not require systemic antibiotics but should be managed with early debridement, appropriate topical and/or biological dressings, and scheduled dressing changes.[27] Topical therapy is not intended to sterilize the burn wound but to control colonization. Gauze and sterile dressings are used for coverage to minimize evaporative water losses.[139]

Topical Therapy

The choice of topical agent depends on the depth and extent of the wound being treated. Minor superficial burns can be treated with moisturizing creams such as Eucerin or aloe. Superficial partial-thickness burns to the face are treated in a similar fashion. Nonadherent gauze or petroleum gauze can be placed over triple antibiotic ointment to provide a comfortable, protective environment that promotes epithelialization. After cleansing and debridement of deeper burns, topical agents including silver sulfadiazine (Silvadene), mafenide acetate (Sulfamylon), and silver nitrate are options for local care.[27] Silvadene has been used in burns for decades and continues to demonstrate effective control of burn wound colonization against a continually widening spectrum of bacteria. Drawbacks include minimal eschar penetration and complications related to leukopenia and red blood cell hemolysis.[140] Sulfamylon cream is also easy to apply but is more painful when used on superficial partial-thickness burns. Eschar penetration is greatest using this agent, making it the topical of choice in burns where eschar will not be excised immediately. Its antimicrobial activity includes control of *P. aeruginosa,* a common colonizing bacterium in pediatric burn patients.[27,140] Sulfamylon is a carbonic anhydrase inhibitor, and complications related to metabolic acidosis may occur. Although these two agents are used most often in care of pediatric burns, silver nitrate 0.5% solution has generally fallen out of favor as first-line therapy due to electrolyte abnormalities and poor tissue penetration.

Newer bioactive dressings have begun to replace topical antimicrobials, as they minimize the need for twice-daily dressing changes. Silvadene in particular has been shown to delay wound healing due to direct toxic effect on keratinocytes, in addition to traumatic injury caused by frequent reapplication.[141,142] Newer agents such as hydrocolloid, hydrogel, and polyurethane film dressings provide effective humidity and control of exudate but are lacking in antimicrobial coverage. Silver-impregnated dressings such as Acticoat, Aquacel, and Mepilex provide combined antimicrobial coverage, adequate humidity for the wound, and decreased trauma to healing

wounds with less frequent dressing changes.[27] Biosynthetic substitutes such as Biobrane are marketed as epidermal substitutes that allow for faster re-epithelialization.[143] These agents are useful for partial-thickness burns seen early in a burn center before bacterial colonization has taken place.

Surgical Treatment

In addition to topical treatments, larger burns treated in the inpatient setting are managed with surgical excision and placement of xenograft, allograft, autograft, or cultured epithelial autografts (CEAs). Placement of skin substitutes and replacements requires adequate wound bed excision and preparation.[27] Use of these materials on eschar or an improperly prepared wound bed will lead to graft loss and prolongation of definitive therapy. Although no consensus exists on the timing of burn wound excision, most experienced burn surgeons advocate early wound excision within the first 1 to 5 days after thermal injury to attenuate the inflammatory response of burn and reduce the risk of sepsis.[144,145] At our institution, a staged approach is often taken for more extensive injuries whereby the wound is excised and controlled on day 1 with subsequent donor site harvest and grafting.[27] The benefits of this approach include shorter operations, tighter temperature control, and ability to perform sheet grafting through improved hemostasis. Additional research is being performed to evaluate adjuncts including laser Doppler imaging to assess for cutaneous blood flow within burn wounds to best assess appropriate time and wound bed for grafting.[31]

Xenograft (pig skin) is a less expensive alternative to allograft (human cadaver skin) for coverage of burn wounds. It is incapable of engraftment and best used for temporary coverage, providing effective protection.[27] Allograft has revolutionized burn care by providing medium-term coverage for patients requiring excision without available autograft. Allograft is typically rejected within 2 to 3 weeks after placement, although burn patients demonstrate differences in immunocompetence resulting in varying degrees of rejection. Autograft provides definitive coverage of deep partial- and full-thickness burns. Donor site selection depends on available areas and extent of burn to be covered, and if limited, xenograft and allograft are provide effective temporizing coverage. Autograft can be applied as sheet graft or can be meshed in ratios from 1 : 1 up to 4 or 6 : 1.[27] Using large mesh grafts more than 2 : 1 is becoming uncommon even in treatment of large burns because of improved local wound management techniques and availability of synthetic skin substitutes.

Cultured epidermal autografts (CEAs) are derived from the individual patient's own cells and were first successfully used in the 1980s.[146,147] However, these thin grafts are fragile, difficult to work with, take 2 to 3 weeks to grow, and usually result in hypertrophic scarring and unstable epithelium. For these reasons, CEAs are usually reserved for burns greater than 85% TBSA. For the past 2 decades, our institution has made use of a cultured skin substitute consisting of autologous keratinocytes and fibroblasts grown on a collagen-based scaffold.[148,149] Our use of the cultured skin substitute leads to fewer complications related to placement and healing postoperatively, as well as less hypertrophic scarring and improved aesthetic results.[150]

Burn Prevention

The best, most cost-effective care for pediatric burn patients will always be prevention of the initial injuries. The vast majority of pediatric burns occur within the home, and the most powerful method of prevention lies in education. Distribution of informative brochures and web-based educational modules can help expand current burn safety and prevention programs to schools and the surrounding communities.[151,152] Strict building codes, regulation of fireworks and highly flammable products, and product modification including newer safety standards within the industries of children's clothing and toys are vitally important from a regulatory level to combat preventable fire-related injury. Residential fires can be battled with routine practice of Exit Drills in the Home (EDITH) with children and occupants, as well as routine smoke detector testing. Scald burns can be prevented by regulation of home hot water heaters to temperatures between 120 and 130 degrees Fahrenheit, as well as device modification to prevent children from turning on hot water faucets.[153] Both the Flammable Fabric Act, passed in 1967, and additional safety standards for children's pajamas attempt to combat additional morbidity from burn injury.[153] While all risk factors are not modifiable, the extensive morbidity and mortality extending from burn injuries within the pediatric population is best treated with the multifaceted, team-based approach of wound management by burn specialists, supportive care, and injury prevention.

SECTION XI

Pediatric Trauma

OUTLINE

CHAPTER 118

Evaluation, Stabilization, and Initial Management After Multiple Trauma

Alan H. Tyroch, Susan F. McLean, Chet Moorthy

PEARLS

- The primary survey, as defined by Advanced Trauma Life Support, is a prioritized evaluation and management protocol focused on identifying and treating the most life-threatening injuries first.
- Injured children who present to the emergency department can be divided into three categories with respect to initial airway management: those with a patent airway requiring no manipulation, those who have undergone interventions in the field or at another hospital to establish a patent airway, and those who will need intervention to establish a patent airway. The first group is the most common.
- The most effective, objective, and rapid steps in evaluating breathing and adequate ventilation are auscultation of the chest, application of a pulse oximeter for measurement of oxygen saturation, and assessment of respiratory rate.
- The greater physiologic reserve of children makes early identification of cardiovascular compromise more difficult than in adults. Assessment and management of circulatory status in the primary survey is focused on early identification and treatment rather than defining the specific etiology of the shock state.
- Of the three main components of the Glasgow Coma Scale, the motor score has been shown to be the best predictor of outcome after injury.

Trauma is the leading cause of death and acquired disability in children and adolescents, resulting in more deaths in children than all other causes combined.[1,2] Because children with severe injuries can rapidly deteriorate, resources for rapidly identifying and treating injuries are needed immediately on arrival at the receiving

hospital. The initial evaluation of injured children in the emergency department ("trauma resuscitation") has two main goals: (1) identify and immediately treat potentially life-threatening injuries and (2) determine disposition after the trauma resuscitation on the basis of known or suspected injuries. The trauma team must stabilize the child, determine the extent of the injury, and develop an initial treatment plan for the child's hospitalization.

Advanced Trauma Life Support (ATLS) is a protocol developed to standardize the initial evaluation and management of injured patients and avoid omission of potentially lifesaving interventions. The ATLS training program was initiated by an orthopedic surgeon in 1978 in response to suboptimal care that he and his family received in a rural hospital after an airplane crash in a Nebraska cornfield. After 4 decades of refinement, ATLS serves as the standard for the initial management of injured patients and is now taught to providers around the world.[2] The impact of ATLS on reducing morbidity and mortality after injury has been affirmed in several studies.[3,4] ATLS training is mainly focused on treating the injured adult but includes modules that emphasize the anatomic, physiologic, and psychologic features that make management of the injured child unique.

The first phase of ATLS is the *primary survey* and is a rapid evaluation for identifying life-threatening injuries. The steps include evaluation and treatment of airway injuries (A, *airway*) followed by evaluation of respiratory dynamics (B, *breathing*), evaluation of the patient's hemodynamic status (C, *circulation*), followed by a neurologic assessment (D, *disability*). The final phase of the primary survey (E, *exposure/environment*) includes removing the patient's clothing to identify concealed injures and ensuring that the patient is protected from environmental heat loss. The primary survey is then followed by the secondary survey, which is a detailed head-to-toe evaluation that identifies other injuries. The steps within the primary survey are repeated as needed if the patient's status changes and to monitor the response to therapeutic interventions. The initial management of injured adults has been the domain of trauma surgeons; however, the jurisdiction of care for the injured child is not as well defined at many centers. Frequently, pediatricians, anesthesiologists, and emergency department physicians have an active role in the initial management and treatment of injured children.[5] Although formal ATLS training is not needed for most pediatric providers, this training should be mandatory for those actively involved in the initial evaluation of injured children. The goal of this chapter is to provide a focused introduction to the initial resuscitation of injured children. This chapter does not serve as a replacement for ATLS training but will instead highlight aspects of the resuscitation that are unique to injured children or may not be emphasized in the ATLS curriculum.

Prehospital Care and Trauma Team Activation

Initial field care, appropriate triage, and rapid transport are all aspects of prehospital care that can have an important impact on the outcome in pediatric trauma. Cities and regions have developed trauma systems that coordinate these aspects of care by creating networks of prehospital and hospital providers. The most severely injured children are triaged to the centers within each trauma system that have the personnel, facilities, and equipment to manage these patients. Equally important, minimally injured patients can be directed to nontrauma hospitals to avoid

burdening pediatric trauma centers with these patients. Field triage is based on several components including physiologic criteria, anatomic injury, mechanism of injury, and underlying medical conditions. Triage criteria are designed to minimize inappropriate transport of severely injured patients to nontrauma hospitals (undertriage) but achieve this goal at the cost of directing some patients to trauma centers who are only minimally injured (overtriage). Due to the limited time and resources available for evaluation in the prehospital setting, overtriage is an unavoidable aspect of current trauma systems. Injured children who have met criteria for transport to high-level trauma centers by current criteria may be minimally injured and require no specific interventions before discharge from the emergency department. A key aspect of the initial management of the injured child in the emergency department is effectively continuing the care started in the field while avoiding unneeded care for those with minimal injuries.

One approach that has been used in many centers to address the problem of overtriage is the use of a tiered team response in the emergency department.[6] On the basis of prehospital criteria, patients who are identified as being most at risk for severe injury are met by a full team upon arrival including a trauma surgeon, emergency department physicians, critical care physicians, anesthesiologists, nurses, and radiology technicians. Patients with a lower likelihood of severe injury are initially met by a smaller team with the option of summoning a larger team if the initial evaluation suggests a severe injury. Centers that have used this approach for team activation have significantly reduced the expenditure of resources on minimally injured patients without any impact on the care received for more severely injured patients.[7]

Trauma Resuscitation

Trauma resuscitations are among the most resource-intensive and time-pressured events in any hospital. The severity of the patient's injuries, number of team members required, and number of simultaneous evaluation and management steps needed contribute to the complexity of the environment. To manage the complexity of trauma resuscitation, a systematic team-based and process-focused approach is needed to rapidly identify and treat life-threatening injuries and minimize team errors.

Designating a specific room and team for trauma resuscitations helps ensure that the needed resources are immediately available. A single location ensures that supplies (eg, emergency airway kits, chest tube and thoracotomy trays, and central or intraosseous vascular access kits) are available and that team members know to gather at a specific site. Physicians, nurses, radiography technicians, respiratory therapists, and other hospital personnel needed for trauma resuscitation are identified in advance as trauma team members assemble and assume their roles in the resuscitation area upon arrival of the injured child (Fig. 118.1). These seemingly simple preparations ensure that the arriving patient has the maximal resources available at the receiving hospital. It is especially helpful to have a resuscitation room equipped with pediatric age and size specific equipment. Special carts, with color-coded drawers matching the Broselow measuring device, are helpful to organize size specific equipment.

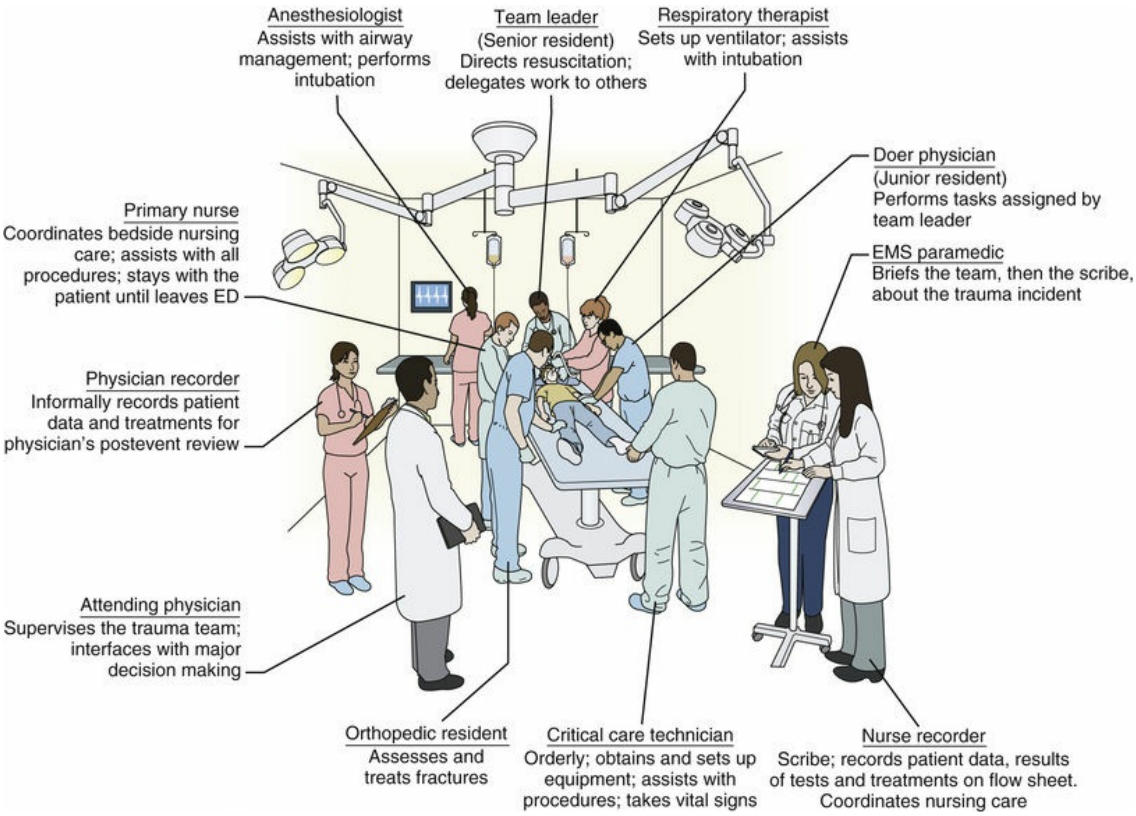

FIG. 118.1 The trauma room and team. (From Sacrevic A, et al. Quantifying adaptation parameters for information support of trauma teams. CHI 2008 Proceedings.)

Before arrival at the hospital, prehospital providers transmit information to hospital providers regarding the mechanism of injury, status of the patient, and initial treatments or interventions that have been provided. This information can alert the team to prepare specific equipment or resources or to summon other essential personnel. Before the patient arrives, it is good practice for the team to review prehospital information to ensure all team members are aware of the patient's status and anticipated needs. On arrival at the emergency department, an additional and final exchange of information between the prehospital providers and the trauma team occurs. A "time out" or quiet period facilitates this information transfer. Essential elements that should be obtained in this report include details about the injury event, vital signs obtained at the scene and during transport, pertinent physical findings, and the initial treatments administered and response to these treatments.[8] Allowing the prehospital providers to give their report before starting the patient evaluation or even transferring the patient to the emergency department gurney improves information exchange and prevents repetitive questions later in the resuscitation. Obtaining a record of the prehospital event completes the formal information exchange between prehospital and in-hospital providers. These records can contain critical information for early in-hospital management but often are not immediately obtained because prehospital providers are moving on to their next assignment and the trauma team is focused on direct care of the patient.

Primary Survey

Overview

The primary survey, as defined by ATLS, is a prioritized evaluation and management protocol focused on identifying and treating the most life-threatening injuries first. This approach is different from the traditional initial evaluation in a patient in which an extensive history and physical examination are performed before diagnosis and treatment. The steps of the primary survey are taught in the ATLS course as a sequence followed by one provider with one nurse. In actual practice, most centers have a team of providers rather than only two, allowing the evaluation and management steps to proceed forward in parallel even if one step leads to a delay. A designated team leader stands at the foot of the bed, receives information reported by the team, and provides higher-level direction of the conduct of the resuscitation. While the steps of the primary survey provide the framework for the initial assessment, new information may be obtained in later phases or a patient's status may change, requiring iterative performance of each step. It is often a challenge to ensure the team retains its focus on the underlying prioritization scheme of the primary survey and does not omit or minimize steps in this process (Fig. 118.2).[2] When resuscitations are evaluated, compliance with ATLS protocols is often low, mandating continued training and retraining to ensure the well-established benefits of this protocol are realized.[9]

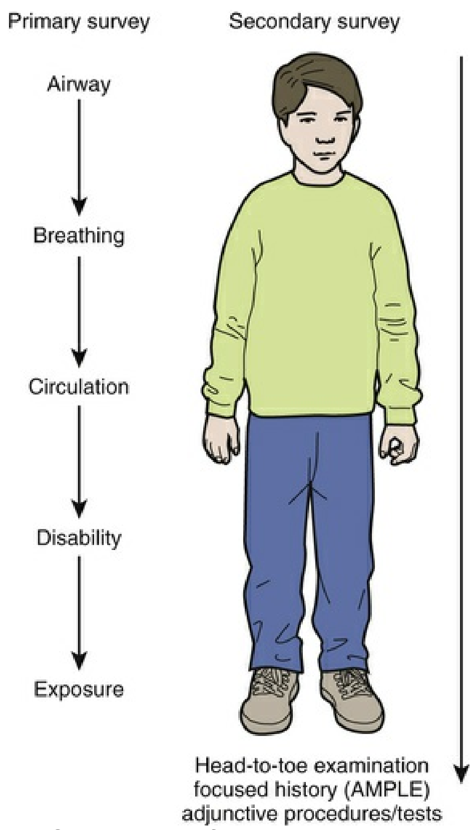

FIG. 118.2 Schematic of initial trauma resuscitation.

Establish an Airway With Cervical Spine Stabilization

(A)

Establishment of a patent airway with cervical spine stabilization is the first step of the primary survey. All patients should immediately receive oxygen as the evaluation is begun. After oxygen is placed, evaluation of the airway can proceed. Injured children who present to the emergency department can be placed into three categories with respect to initial airway management: (1) those with a patent airway requiring no manipulation, (2) those who have undergone intervention in the field or at another hospital to establish a patent airway, and (3) those who will need an intervention to establish a patent airway. Most children evaluated by the trauma team are in the first group. For these patients, evaluation should include several simple steps including asking the patient's name, inspection for craniofacial injuries, assessment for voice changes, and listening for obvious stridor. These steps can be performed easily and rapidly in most children. A simple statement that “the airway is patent” will communicate to the team that these confirmatory steps have been accomplished. Because most injured children will not require any specific airway management, omission of elements of the airway assessment is common in pediatric trauma resuscitation. In a study of pediatric trauma resuscitations analyzed by video review, the most common omission in airway evaluation was not providing supplemental oxygen (omitted in 67% of resuscitations). Less than one-quarter of resuscitations included a complete assessment of the airway along with assessment of “breathing,” the second component of the primary survey.[10] Although the patency of the airway may seem “obvious” in many patients, subtle and early signs of pending airway compromise will be missed if a formal airway evaluation is not completed (Table 118.1).

TABLE 118.1

Missed Components of the Primary and Secondary Survey in Pediatric Trauma Resuscitation: Management Errors Among All Patients (*N* = 90)

Errors Identified	*N* (%)
Airway and Breathing	
Delay in oxygen therapy	60 (67)
Chest not auscultated	40 (44)
Oxygen saturation not measured	33 (37)
Neck not adequately examined	71 (79)
Cervical Spine	
No head stabilization on transfer	18 (20)
Circulation	
Inappropriate IV access	18 (20)
Pulse not assessed	37 (41)
Central capillary refill not assessed	59 (66)
Blood pressure not measured	28 (31)
Fluid bolus not warmed	33 (89)
Disability	
Pupils	22 (25)
Posture	22 (25)
Secondary Survey	
Perineum not examined	41 (45)
Head not examined	13 (15)

Modified from Oakley E, Stocker S, Staubli G, et al. Using video recording to identify management errors in pediatric trauma resuscitation. Pediatrics. 2006;117:658-664.

The second category is children with an airway already established in the field or other hospital, usually by endotracheal intubation. Airway interventions performed before a patient's arrival should not be interpreted as an adequate airway, and additional steps should be performed to assess airway patency, especially in light of the relative tenuous nature of pediatric airways placed under emergency situations.[11] The key steps to evaluating an endotracheal tube placed outside the emergency department are assessing the appropriateness of tube size, evaluating tube depth, assessing adequacy of ventilation by auscultation and inspection of the chest, measurement of end-tidal CO_2, and confirmation of tube position with a chest radiograph. The appropriate tube size can be evaluated using age-specific formulas and charts or by comparing the tube with the child's fifth (little) finger. Deep placement of an endotracheal tube in a prehospital setting is common, especially among younger children. In addition, the shorter airway of children increases the likelihood that an endotracheal tube will migrate from the proper position during transport. An easy rule for rapidly assessing tube depth is that the length of the tube at the teeth should be three times the tube size (internal diameter measured in mm). Age-specific formulas for evaluating endotracheal tube depth are available and are more easily used by providers with greater experience in airway management. Assessment that the endotracheal tube is an adequate airway should include steps that are more formally part of the breathing (B) phase of the primary survey, including assessment of ventilation by auscultation and inspection and measurement of end-tidal CO_2. Because of a shorter airway and relatively less margin for movement of an endotracheal tube in younger child, correct endotracheal tube position cannot be reliably confirmed by auscultation of bilateral breath sounds alone.[12] Final confirmation of endotracheal tube position requires a chest radiograph. In most cases, the chest radiograph should be deferred until later in the resuscitation because simpler and more rapid evaluations can be performed to verify tube position that do not interrupt the conduct of the primary survey. However, a chest radiograph should be performed in the emergency department before transport to other areas of the hospital to avoid the need for airway management in less optimal hospital settings.

The final category of injured children undergoing airway evaluation is those who present with airway compromise requiring intervention. Because this category of injured children is least common, clearly defined personnel and procedures are needed to prepare the team to efficiently and safely establish an airway. Indications for endotracheal intubation in pediatric trauma include apnea, inability to maintain a patent airway by other means, a need to protect the lower airway from aspiration of blood or vomitus, impending or potential compromise of the airway, presence of a closed head injury with a Glasgow Coma Scale [GCS] score ≤8, and inability to maintain adequate oxygenation with supplemental face-mask oxygen.[2] An altered level of consciousness, usually due to an intracranial injury, is the most commonly observed reason for emergency airway intervention in the acutely injured child. Although a neurologic assessment is performed later in the primary survey, early recognition of children requiring a formal airway because of an altered level of consciousness is essential. The AVPU scale (***a***wake, responds to ***v***erbal stimuli, responds to ***p***ainful stimuli, and ***u***nresponsive) is one model for assessing

consciousness that has been found to correlate with the GCS scale and which may be useful for identifying children who are at risk for a compromised airway because of an altered level of consciousness.[13] Patients with an AVPU score of "P" or "U" can be anticipated to have a GCS score of 8 or 3, respectively, and should receive early airway intervention with endotracheal intubation.[14]

Once the trauma team has confirmed the need to establish an airway, the least invasive method for achieving this goal should be chosen. A chin lift and jaw thrust may be sufficient for initially opening the airway in some patients and are simple and rapid steps that can facilitate bag-valve-mask ventilation. However, in the presence of a suspected cervical spine injury, only a jaw thrust should be used. Because these maneuvers are not sufficient for long-term airway management, further interventions are necessary to establish a definitive airway. Small children on a flat spine board may have a partially occluded airway because their proportionately large head forces the neck into a kyphotic (flexed) position, resulting in upper airway obstruction. Simple manipulation of the young child's head to maintain the plane of the face parallel with the plane of the spine board can improve airway patency.

When a more definitive airway is necessary, the preferred method for establishing an airway in pediatric trauma is orotracheal intubation. A rapid-sequence technique is preferred for most injured children because endotracheal intubation is made easier by eliminating protective airway reflexes and safer by preventing aspiration and decreasing physiologic stress that can lead to increased intracranial pressure in children with a traumatic brain injury.[15] During endotracheal intubation, steps should be taken to account for the short length and narrow diameter of the trachea, including choosing an appropriately sized endotracheal tube and confirming tube position. Nasotracheal intubation is usually not performed for injured children because this technique is more difficult due to the acute angle of the posterior pharynx of the child, may result in trauma with bleeding, and increases intracranial pressure. Nasotracheal intubation is also contraindicated in patients with facial trauma, cerebrospinal fluid leaks, or suggestions of basilar skull fractures because these injuries suggest the possibility of a disruption between the cranial vault and the nasopharynx.[16,17] The laryngeal mask airway (LMA) is also an option for emergency airway management in situations in which endotracheal intubation cannot be accomplished.[17-19] However, as the LMA does not protect against aspiration and cannot be used effectively to provide positive pressure ventilation in patients with altered respiratory compliance or resistance, it should be used only as a rescue technique if the patient's trachea cannot be intubated.[20]

Less than 1% of all adult patients who require an emergency airway in the emergency department require a surgical airway.[21] The percentage of children requiring an emergency airway after injury is likely to be even smaller. Among injured children with a compromised airway, endotracheal intubation may not be possible because of significant craniofacial injuries, massive bleeding from the nasopharynx or oropharynx, or preexisting anatomic features such as a short neck, micrognathia, or small mouth that make intubation more difficult. In this "cannot intubate/cannot ventilate" subset, a systematic approach is necessary to rapidly secure a patent airway (Fig. 118.3).[20]

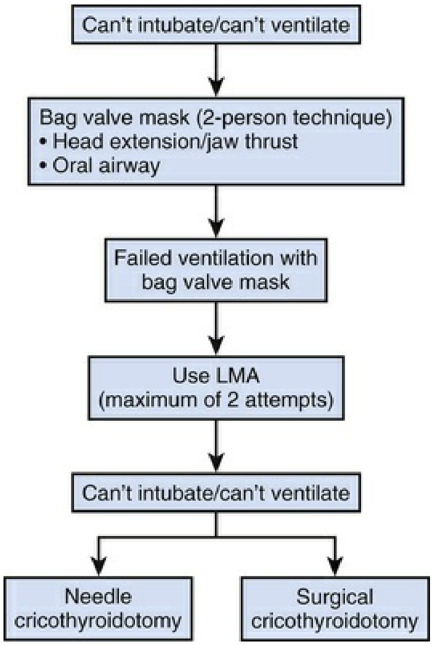

FIG. 118.3 Flow chart for "can't intubate/can't ventilate" airway emergencies. (Modified from Henderson JJ, Popat MT, Latto IP, et al. Difficult Airway Society guidelines for management of the unanticipated difficult intubation. Anaesthesia. 2004;59:675-694.)

If bag-valve-mask ventilation is successful, the team has time to find alternative routes of securing an airway. Examples include bringing a more experienced physician to the trauma bay to assist with establishing an airway or using alternative techniques such as indirect laryngoscopy or fiberoptic intubation. If bag-valve-mask ventilation is not successful, an appropriate invasive procedure may be required. Among injured children, appropriate options include surgical or needle cricothyrotomy, depending on the child's size. Among children with a larger airway whose cricothyroid membrane is easily palpated, a surgical cricothyrotomy is preferred.[2] If small neck size or other anatomic features preclude the safe placement of a cricothyrotomy, a needle cricothyrotomy with needle jet insufflation of oxygen into the airway has been recommended. However, given the difficulties and potential morbidity related to the technique, there remains controversy regarding its use in younger children and infants (see later). Surgical cricothyrotomy should be performed by members of the team with experience with this technique. This procedure has four main steps: (1) identification of the cricothyroid membrane, (2) making an incision through the skin and cricothyroid membrane, (3) stabilization of the larynx with a tracheal hook at the inferior aspect of the ostomy, and (4) placement of a tube in the trachea.[22] Although controversy surrounds whether needle cricothyrotomy should be used at all in pediatric patients, it is still advocated by some authorities as a rescue technique in specific clinical scenarios. Needle cricothyrotomy can be performed using commercially available kits. When one is not available, the procedure can be carried out by inserting a large-bore (12- to 18-gauge) angiocatheter in a caudal direction at a 30- to 45-degree angle through the cricothyroid membrane. During needle advancement, constant negative pressure is applied to the plunger of the syringe to aspirate air and confirm its endotracheal position.[23] After confirmation of endotracheal placement, the syringe and stylet are removed and the cannula is connected to an oxygen source. Among larger children and adolescents, the cannula should be connected to an unregulated oxygen supply

of 50 psi because ventilation cannot be adequately provided using an Ambu bag.[24] While pediatric evidence is limited, a flow of 25 to 35 psi from a standard regulator set at 10 to 12 L/min for most children has been recommended. Another approach that can be used is based on flow rates and estimated tidal volumes (TVs): 10 to 25 psi with TV of 340 to 625 mL for children 8 years and older; 5 to 10 psi with TV of 240 to 340 mL for children 5 to 8 years old; and 5 psi with TV of 100 mL for patients who are 5 years and younger.[23] Standard IV tubing can be connected to the cannula, and a Y-connector can be placed between the IV tubing and oxygen tubing. Intermittent occlusion for 1 second and release of the Y-connector for 4 to 5 seconds provides some passive ventilation. A needle cricothyrotomy is a highly tenuous airway and should be carefully secured after placement and converted to a more stable airway as soon as possible. This approach is only sufficient for 30 to 45 minutes because of the progressive respiratory acidosis that results from underventilation.[2] Because surgical airway management is rarely performed in pediatric patients, centers that manage injured children should have the equipment and adequately trained personnel for performing these procedures when needed.

Cervical spine stabilization should be viewed as part of the “A” step and is included as part of airway management in ATLS. Endotracheal intubation in the trauma bay should proceed with the assumption that a cervical spine injury is present until this type of injury has been formally ruled out. This step is needed in patients with any mechanism of injury that can be associated with cervical spine trauma. Many injured children present to the emergency department with a cervical collar that was placed in the field because of the mechanism of injury. The initial evaluation of the airway should be immediately followed or simultaneously performed with an assessment of the proper size and fitting of the cervical collar or placement of a cervical collar when one is not present. When endotracheal intubation is required, in-line cervical spine stabilization should be used. A member of the team holds the neck on each side with his or her hands and forearms maintaining the stability of the spine during airway manipulation. Despite the importance of this step, neck inspection and palpation while maintaining C-spine precautions and head stabilization during transfer to the trauma gurney are steps omitted in 80% and 20% of trauma resuscitation performed for injured children, respectively.[10]

Breathing (B)

Establishment of a patent airway is an important initial step but is not sufficient to ensure adequate oxygen delivery. The breathing (B) step of the primary survey is the immediate assessment of ventilation and performance of measures to establish adequate ventilation if it is compromised. The three most effective, objective, and rapid steps in evaluating ventilation are auscultation of the chest, application of a pulse oximeter for measuring oxygen saturation, and assessment of respiratory rate. Because patients are supine during the primary survey, auscultation is limited to the anterior and lateral chest. Auscultation should be performed in both these areas to obtain the most accurate evaluation of ventilation. Localizing abnormal auscultatory findings to a specific region of the chest can be more difficult in younger children because of smaller chest size and the usual supine position of the injured patient during the primary survey. However, in most children, auscultation can be used to identify significant compromise in ventilation requiring lifesaving intervention.

These steps can be supplemented by a subjective evaluation of the adequacy and symmetry of chest wall movement and an evaluation for evidence of chest wall trauma. Because of the pliability of the chest wall of younger children, significant chest injury may be present even in the absence of any chest wall deformity.

A main focus of the B phase of the primary survey is identifying four specific thoracic injuries that can significantly impair ventilation and that require immediate treatment: (1) tension pneumothorax, (2) open pneumothorax, (3) flail chest with pulmonary contusion, and (4) massive hemothorax. The diagnosis of a tension pneumothorax should be made on clinical criteria, including tracheal deviation, unilateral absence of breath sounds, neck vein distention, tachycardia, hypotension, and respiratory distress. Delaying treatment to obtain a confirmatory chest radiograph should be avoided because of the time delay associated with processing and interpreting this study. When the clinical diagnosis of a tension pneumothorax is made, the chest should immediately be decompressed by placing a 14- to 18-gauge, 5-cm needle into the second intercostal space at the midclavicular line. The needle should be sufficiently long to penetrate the chest wall and enter the pleural space. A minimum length of 5 cm is recommended in older children and adults, but shorter needles may suffice in infants and younger children.[2] Proper intrathoracic placement of the needle can be partly confirmed by an audible rush of air when entering the chest. Because needle decompression will convert a tension pneumothorax into a simple pneumothorax, a chest tube will be necessary regardless of the response to needle decompression. If a child arrives after needle decompression, tube thoracostomy placement will most likely be necessary for definitive treatment.

An open pneumothorax or "sucking chest wound" occurs when the size of a chest wall injury approaches two-thirds the area of the tracheal lumen, causing a preferential pull of air into the pleural space and out of the wound. This injury can lead to mediastinal shift, decreased venous return, and eventual cardiopulmonary collapse. Open pneumothorax is rare in children and is usually the result of a penetrating injury. Airflow through the wound will be audible or can be visualized by bubbling of blood at the wound. A semiocclusive rectangular petroleum jelly/gauze dressing that is occlusive on three sides beyond the wound edge will produce a one-way valve effect that will allow air to escape on expiration but inhibit air from entering the thoracic cavity on inspiration.[25]

Flail chest occurs when a segment of the chest wall has lost continuity with the movement of the thoracic cage, occurring when two or more ribs are fractured in two or more positions. The pediatric thoracic cage is more compliant than adults, and rib fractures are not always present when parenchymal injuries exist. When occurring in infants and young children, rib fractures suggest a significant amount of blunt force to the chest and the possibility of an underlying pulmonary contusion, as well as hepatic or splenic injury. Because fractured ribs can lead to direct lung injury, the presence of a flail chest segment should raise the suspicion of a pneumothorax and hemothorax. Due to compromised ventilatory function and underlying pulmonary injury, management of flail chest is focused on providing temporary ventilatory support until the injury heals. Intubation may be immediately necessary in the emergency department when ventilation is significantly compromised by this injury.

Significant bleeding may occur with thoracic trauma from intercostal vessels,

internal mammary vessels, lung parenchyma, or cardiopulmonary vessels, leading to massive hemothorax. Children with this injury will present with decreased breath sounds and dullness to percussion on the affected side. Eliciting the finding of dullness to percussion can be difficult in a noisy trauma resuscitation area but is a diagnostic feature that can be used to distinguish this injury from a pneumothorax. While the diagnosis is optimally made with a chest radiograph, the team should proceed with immediate chest tube placement if clinical evidence suggests the presence of a large amount of intrathoracic blood. When a massive hemothorax is present, fluid resuscitation or blood transfusion will often be necessary. After chest tube placement, the amount of blood initially obtained and the rate of continued bleeding from the tube should be evaluated. A thoracotomy for controlling bleeding from the chest wall, lung, or heart may be indicated if the initial volume exceeds 20% to 25% of estimated blood volume, bleeding continues at a rate exceeding 2 to 4 mL/kg/hr, the rate of bleeding is increasing, or the pleural space cannot be drained of blood and clots. The latter three criteria may be observed after the child is initially stabilized and has been admitted to the hospital.

About 75% of traumatic chest injuries can be treated expectantly or with placement of a chest tube and volume resuscitation.[26] Although placement of a chest tube in an injured child is similar to placement in other settings, additional steps should be considered in the injured child. When placing a chest tube for trauma, the tube should be directed posteriorly to allow for adequate drainage of blood in a supine patient. A sufficiently large tube should be selected to allow drainage of blood and fluid without becoming clogged with blood clot. The fifth intercostal space (nipple level) in the anterior midaxillary line is ideal in most patients to prevent placement of the tube through the diaphragm or abdomen but allows sufficient length in the chest for drainage and avoiding later dislodgement. Confirmation of tube placement in the pleural space can be confirmed in infants and smaller children by the egress of air or blood after placement. Proper tube placement in the thoracic cavity can also be evaluated by observing air condensation on the internal surface of the tube and movement of fluid in the water-seal chamber in time with the patient's respirations when connected to a pressure-regulated collection device. A chest radiograph should be performed to verify placement of the tube before leaving the resuscitation area.

Circulation (C)

The “C” step of the primary survey is the assessment, recognition, and management of shock. Because of greater physiologic reserve, early identification of cardiovascular compromise can be more difficult in children than adults (Table 118.2). Assessment and management of circulatory status in the primary survey are focused on early identification and treatment rather than defining the specific etiology of the shock state. Determining the site of internal hemorrhage and defining the specific type of shock state are steps that are deferred until after the primary survey. Objective assessment of circulation is done by measuring heart rate and blood pressure and assessing pulses and capillary refill. In addition to cardiovascular compromise, tachycardia after injury can indicate pain, fear, or other psychologic stress. Tachycardia therefore cannot be used as the sole criteria for diagnosing cardiovascular compromise and needs to be combined with other clinical

criteria before treatment is initiated. A manual blood pressure measurement should be obtained, using the appropriate size cuff, on arrival to the resuscitation area. Periodic reassessment of blood pressure should continue throughout the resuscitation to verify the child's hemodynamic status. Palpation of central and peripheral pulses is a rapid method for detecting hypotension and often can be accomplished before a cuff blood pressure is obtained. Because pulses are most likely to be lost in progressive hypotension in the wrist or feet followed by the groin and then by the neck, palpation for pulses in each of these areas can provide a crude estimate of the level of hypotension. Assessment of peripheral perfusion can also include an estimate of capillary refill in addition to a visual evaluation of skin perfusion. Because these latter assessments are more subjective, these should be used only in conjunction with more objective measurements in directing treatment. While assessment of circulatory status is essential to the initial evaluation of an injured child, these steps are often omitted or delayed until later in the resuscitation. During video review of pediatric trauma resuscitations, blood pressure was not measured in 31% of patients, pulses not assessed in 41%, and central capillary refill not assessed in 66% during the initial evaluation.[10] One important item to remember when assessing children after trauma is that pediatric patients will often maintain blood pressure and cardiac output by increasing heart rate. Children become hypotensive at later stages of shock.

TABLE 118.2

Systemic Responses to Blood Loss in Pediatric Patients

System	Mild Blood Volume Loss (<30%)	Moderate Blood Volume Loss (30%-45%)	Severe Blood Volume Loss (>45%)
Cardiovascular	Increased heart rate; weak, thready peripheral pulses; normal systolic blood pressure (80-90 + 2 × age in years); normal pulse pressure	Markedly increased heart rate; weak, thready central pulses; low normal systolic blood pressure (70-80 + 2 × age in years); narrowed pulse pressure	Tachycardia followed by bradycardia; very weak or absent peripheral pulses; hypotension (<70 + 2 × age in years); narrowed pulse pressure (or undetectable diastolic blood pressure)
Central nervous system	Anxious; irritable; confused	Lethargic; dulled response to pain[a]	Comatose
Skin	Cool, mottled; prolonged capillary refill	Cyanotic; markedly prolonged capillary refill	Pale and cold
Urinary output[b]	Low to very low	Minimal	None

[a]The child's dulled response to pain with this degree of blood loss (30%-45%) may be indicated by a decreased response to IV catheter insertion.

[b]After initial decompression by urinary catheter. Low normal is 2 mL/kg/hr (infant), 1.5 mL/kg/hr (younger child), 1 mL/kg/hr (older child), and 0.5 mL/hg/hr (adolescent). IV contrast can falsely elevate urinary output.

Data from Committee on Trauma, American College of Surgeons. Advanced Trauma Life Support for Doctors, Student Course Manual. 9th ed. Chicago: American College of Surgeons; 2012.

The two main interventions for managing cardiovascular compromise during the primary survey are controlling external hemorrhage and administration of fluid. Active hemorrhage is easy to recognize and can usually be treated by direct manual pressure or the application of compression bandages. Scalp lacerations are a common source of external bleeding in injured children, and blood loss from this site should not be underestimated. A full evaluation for external hemorrhage, however,

is only complete after the child has been exposed completely later in the primary survey.

Administration of fluids requires the establishment of IV access. In pediatric trauma, the preferred order of sites depends on the child's age and the urgency of establishing IV access. If a percutaneous peripheral IV line cannot be established, intraosseous access, percutaneous central venous access, or cutdown on a vein should be considered. Intraosseous access is achieved by placing a needle into the marrow cavity of a long bone in an uninjured extremity. This procedure is rapid, requires minimal training, and is the preferred alternate method of vascular access in infants and younger children. The availability of new equipment and techniques has expanded the use of intraosseous infusions to older children and even adults. Percutaneous placement of a central venous catheter can be pursued as an alternate access in older children when equipment for intraosseous access is not available or when ossification of the long bones precludes placement of an intraosseous needle. Femoral placement of a central line in the injured child has advantages over placement in a jugular or subclavian vein position because it can be performed in most patients without interfering with ongoing assessment and management of other components of the primary survey. However, the femoral route is not recommended if there is concern about the potential for abdominal or pelvic injuries. Despite the importance of establishing IV access in the injured child for fluid resuscitation and administration of medications, vascular access was not performed or inadequate access was obtained in 20% of recorded pediatric resuscitations.[10]

The goal of fluid resuscitation is to rapidly replace intravascular volume, initially with warmed crystalloid solution and then moving to blood products on the basis of the child's response to crystalloid boluses (Fig. 118.4). When cardiovascular compromise is detected, an initial bolus of 20 mL/kg of warmed isotonic crystalloid fluid (normal saline or lactated Ringer solution) should be administered. Given that it is relatively hypotonic, lactated Ringer solution is not recommended for fluid resuscitation in patients with traumatic brain injury. Fluid administration should not be delayed by slow-rate drip infusion but instead should be administered as a bolus using a hand-pump device, syringe, or pressure bag to ensure that the effect of the bolus and assessment of need for additional fluid proceeds rapidly. If a second bolus of crystalloid is necessary, preparations for the administration of blood products should begin. If the child responds to fluid administration, IV fluid is continued at a maintenance rate as further investigations concerning the need for fluid are performed. If there continues to be no response or transient response to crystalloid, blood administration should be considered. During the primary survey, cross-matched, type-specific blood is often not yet available and O-negative blood should be administered. Blood should be administered in boluses of 10 mL/kg. The four sites of hemorrhage that can lead to major blood loss after injury include external sites (eg, scalp laceration), intrathoracic injury, intraabdominal injury, and pelvic or multiple long-bone (usually femur) fractures. While external bleeding can be easily detected, bleeding in other sites is evaluated after the primary survey has been completed.

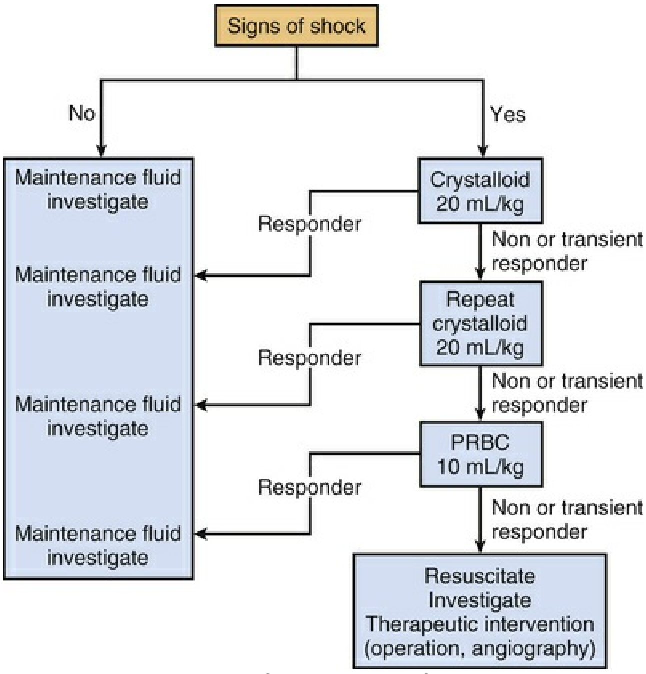

FIG. 118.4 Algorithm for pediatric fluid resuscitation.

Disability (D)

The primary survey continues with a neurologic assessment of the child, the disability (D) component of the primary survey. This assessment includes two main components, calculating the GCS and assessment of pupillary responses (Fig. 118.5). More extensive neurologic evaluation should be deferred to the secondary survey to avoid slowing the primary survey. As with airway assessment, a formal evaluation of GCS is often omitted when it is "obvious" that no neurologic injury is present. This practice should be avoided because subtle changes may be missed with only a cursory assessment. In addition, establishment of a baseline GCS may have prognostic value among children with an evolving intracranial injury. To account for variations in response related to age, the GCS should be calculated using age-specific criteria. Among the three main components of the GCS, the motor score has been shown to be the best predictor of outcome after injury.[27] Particular attention should be paid to ensure that this component is accurately assessed and recorded. Pupillary assessment includes an evaluation of pupil size and response to light and can easily and rapidly be assessed, reported, and recorded. Findings from the neurologic assessment are used to plan additional evaluation and management steps, including the need for endotracheal intubation, the requirements of additional imaging, and the final disposition after leaving the emergency department. Despite the importance of obtaining a GCS and assessing pupils, these steps were both omitted in 20% of observed pediatric trauma resuscitations.

INFANTS	CHILDREN	ADULTS

FIG. 118.5 Components of the Glasgow Coma Scale at different ages.

Exposure/Environment (E)

The final step in the primary survey is exposure of the patient, the "E" component of the primary survey. In this phase, clothing is removed to visually inspect all body regions to minimize the chance of missing an obvious injury. A team-coordinated log roll of the child, maintaining cervical spine stabilization, can be used to assess the back and spine for external injury. When rolled on their side, patients are in an ideal position for assessing the spinal column for deformities and tenderness and for undergoing a rectal examination if indicated. While not all of these steps are formally part of the primary survey, the additional time required for them is minimal, leading to the inclusion of these steps as part of exposure in many centers. Immediately after exposing the injured child, the child should be covered again with warm blankets to minimize heat loss. Infants and younger children are particularly vulnerable to heat loss because of a relatively large surface area in relation to body volume. Other measures for warming or maintaining an injured child's temperature include warming the room and the use of overhead warmers or a Bair hugger. The patient's temperature should be obtained at this point, a step that is frequently omitted in the initial evaluation of the injured child.

Secondary Survey

After completion of the primary survey, the secondary survey is then performed. This includes a medical and event history, a more complete physical examination, and additional adjunct interventions. The secondary survey is less structured than the primary survey, and its components and sequence can be modified to reflect patient needs, provider preferences, and institutional practices. The secondary survey should not be performed until the components of the primary survey have been completed and interventions needed to address issues identified in the primary survey have been implemented. It is a common pitfall to move to components of the

secondary survey or to mix components of the secondary survey during performance of the primary survey. This practice should be discouraged so as to avoid losing focus on the primary survey and life-threatening injuries that it is designed to identify. During the secondary survey, attention should be intermittently refocused on the five vital signs (blood pressure, heart rate, respiratory rate, temperature, and pain score) and other monitoring steps of the primary survey. When changes are observed, the primary survey evaluation and treatment steps should be reinitiated to ensure that potentially life-threatening injuries are addressed.

In contrast to a typical history performed during evaluations in other settings, the history performed in the secondary survey is more focused and follows rather than precedes the performance of the physical examination. It is common practice to obtain this information while simultaneously performing the physical examination components of the secondary survey. The most important history elements to obtain are those that most directly impact injured patients and the evaluation and treatments needed for them. The acronym AMPLE is useful for remembering these key elements (***a***llergies, ***m***edications, ***p***ast medical history, ***l***ast meal, and the ***e***nvironment and events related to the injury). The physical examination contains elements similar to those performed in other settings but should be modified to include steps that identify common and important injuries. Examination of the entire scalp should be performed to identifying lacerations, contusions, or evidence of fractures. Posterior scalp lacerations can easily be missed because of hair or the position of the cervical collar. Massive facial injuries can produce significant facial edema, making the eye examination difficult. Because facial swelling most often worsens with time, it is important to obtain an initial eye examination while the patient is in the emergency department. Fractures to the maxillofacial bones including nondisplaced fractures of the nasal bone, zygomatic arch, and orbital rim can be difficult to detect on physical examination and often require radiographic imaging. Examination of the chest in pediatric trauma can be misleading because severe intrathoracic injury may be present without evidence of obvious skeletal trauma. Abdominal injuries should be aggressively sought in children who have sustained a significant blunt injury to the torso. Repeated examinations are often needed to evaluate for the presence or absence of abdominal tenderness in the anxious child after injury.[28]

Examination of the perineum, rectum, and vagina should be focused on detecting direct trauma and evidence of a pelvic fracture. Digital rectal examination may often be omitted in children with no other signs of injury but should be included if the child sustained significant blunt trauma, has other findings suggesting a pelvic fracture, or has neurologic findings suggesting a spinal cord injury. Any evidence of pain, swelling, or limitation of movement may suggest an underlying fracture and usually warrants radiographic evaluation. The secondary survey should include a more complete neurologic assessment than was performed in the primary survey, as well as a formal assessment of sensory and motor functions.

While the secondary survey can be performed in a free-form fashion, a systematic strategy is necessary to avoid missing key components of this evaluation. In reviews of pediatric trauma resuscitations, components of the secondary survey that are often omitted include examination of the mouth, ears, back, and perineum. As in the primary survey, findings in the secondary survey should be communicated to the

team. The trauma team leader should address the need for tetanus administration (depending on child's vaccine requirements) and antibiotic administration (eg, for open fractures) during the secondary survey.

Missed injuries do occur in trauma resuscitations, which may lead to preventable morbidity during the patient's hospital stay. About 4% of injured children will have an injury missed in the primary and secondary surveys. The risk of a missed injury is higher in children with more severe injuries, including those transported by air, those who undergo endotracheal intubation in the emergency department, those with a low admission GCS, and those with an injury severity score greater than 15.[29] Missed injuries have been shown to be reduced with the implementation of a designated pediatric trauma response team, supporting a focused and stepwise approach to the initial evaluation of the injured children.[30] Critical care providers should be alert to the possibility of missed injuries in patients admitted to their unit and not rely on the emergency department evaluation for detecting all injuries.

Diagnostic Assessment

The secondary survey is supplemented by diagnostic testing that focuses on identifying and treating injuries not found in the primary survey. Performance of a standard set of tests is discouraged to avoid unnecessary discomfort, exposure to radiation from excessive imaging, and cost. Injured children may be overtriaged to the resuscitation area and require no additional testing after the primary and secondary surveys have been completed. Observation in the emergency department before discharge and close outpatient follow-up is an appropriate option for children identified as low-risk for injury. The most important laboratory study to obtain early in the evaluation of the trauma patient is an arterial blood gas (ABG) analysis. This test will identify metabolic acidosis, as well as provide a baseline for hemoglobin and electrolytes. The ABG should be obtained during or soon after the primary survey. When available, a serum lactate can be obtained to evaluate the extent of the primary injury and guide the efficacy of resuscitation.

Laboratory Studies

Routine laboratory evaluations in pediatric trauma have been shown to be of little value in the management of injured children.[31,32] Among children injured from a significant blunt mechanism, a focused screening set of laboratory studies to identify occult intraabdominal or retroperitoneal injury and hemorrhage has been shown to be sufficient. A screening panel that includes aspartate aminotransferase (AST) and alanine aminotransferase (ALT), urinalysis, and hemoglobin will effectively screen for most intraabdominal injuries.[33] The ALT, AST, and urinalysis are screening tests to determine the need for an abdominal CT scan and can be omitted if other clinical indications suggest the need for abdominal imaging. Threshold values of greater than 100 U/L for AST and ALT and more than 5 red blood cells/high-powered field suggest the presence of an intraabdominal injury and suggest the need for abdominal/pelvic imaging.

Among children with major head injuries, penetrating trauma, multiple extremity fractures, and significant mechanisms of injury, this panel of laboratory studies may be expanded to include coagulation studies, electrolytes, and blood for cross-

matching. Coagulation studies in pediatric trauma are most often abnormal in the presence of severe traumatic brain injury. If obtained early after injury, electrolyte studies are most often normal and serve only as a baseline for a patient who will require aggressive management of severe head injuries or aggressive resuscitation. Blood should be obtained for cross-matching if significant fluid resuscitation has been required, the child has a preexisting condition causing a predisposition to bleeding, has a major head injury, or will undergo a surgical procedure with potential for blood loss. Early after injury, pancreatic enzymes do not need to be obtained as a screen for pancreatic injury because of the low diagnostic yield of these studies.[34] Screening tests for alcohol or drug use may be appropriate in older children and adolescent patients.

Radiographic Imaging

Radiographs may be necessary to rule out specific injuries or to evaluate known injuries. The three most common radiographs obtained are cervical spine, chest, and pelvic radiographs. Although these studies are commonly referred to as a *trauma series* and ordered as a set, the performance of all three is often not necessary. The need for each radiograph should be evaluated on the basis of the mechanism of injury and patient symptoms and examination.[35]

A cervical spine injury should be suspected in any child sustaining a significant head injury or injured by a major blunt mechanism. Although cervical spine injuries are rare, these injuries can be devastating and can have worse outcomes when adequate spine precautions are not taken early after injury. A systematic and efficient approach using both clinical and diagnostic modalities is necessary to ensure that a cervical spine injury is not present. Implementation of standards for cervical spine assessment and clearance has been shown to decrease the time for cervical spine clearance.[36] Each institution should develop an institution-specific protocol for managing the initial and subsequent imaging of the cervical spine to avoid either incomplete evaluations or excessive imaging. Criteria for cervical spine imaging include midline cervical tenderness, altered level of consciousness, evidence of intoxication, neurologic abnormalities potentially attributable to a spine injury, and presence of a distracting injury precluding a reliable clinical assessment.[37] The cervical spine evaluation in nonverbal children is particularly difficult to assess. A recent study of this subgroup identified GCS less than 14, GCS eye component of 1, an injury sustained in a motor vehicle crash, and age younger than 2 years as important variables associated with the presence of a cervical spine injury.[38]

A cervical spine series consists of a cross-table lateral, an anterior-posterior view, and an open-mouth view to assess the dens process of C1. With adequate films, a three-view series has a high sensitivity (89%) and a negative predictive value of 99.9%.[39] Among these views, the lateral cervical spine film is most useful and has been adopted as the initial screening film at many institutions.[40] If a patient meets the NEXIS criteria, then the C-spine can be cleared clinically. Cervical CT imaging is indicated if a child has any of the following after a significant mechanism of injury: intracranial injury, any injury above the clavicles, facial fractures, cervical spine tenderness, seat belt sign across the neck, altered mental status with inability to perform cervical spine examination, and intoxication.[41]

Chest radiographs can often be omitted for children without physical examination

findings or symptoms suggesting a thoracic injury.[35] This study, however, should be obtained for children who are injured by a major blunt mechanism such as a high-speed motor vehicle crash or those who have sustained other significant torso injuries. Pelvic radiographs can be safely omitted among children who are awake, alert, and have no physical examination findings or proximity injuries (eg, a proximal femur fracture) to suggest a pelvic injury. Radiographs of the extremities or other areas may also be necessary in the resuscitation area depending on the findings of the primary and secondary surveys. While CT imaging is useful and has the advantages of being rapid and organ specific in defining injuries, there are potential hazards in its use, especially in pediatrics. In 2007, a study from Los Angeles showed that "pan-scanning," or doing a head, chest, and abdomen CT scan, often led to finding unsuspected injuries requiring treatment. Nineteen percent of patients in this study had an injury on CT scan that was not suspected on physical examination.[42] After this study, it became common practice to "pan-scan" many blunt trauma patients. Although rapid and specific, it was soon recognized that patients were being exposed to high doses of ionizing radiation without much proven clinical benefit, as many of the identified injuries did not require surgery. A study from San Antonio in a level I trauma center attached dosimeters to the neck, chest, and groin of the injured children. When a patient underwent CT imaging of more than two body regions, the dose of ionizing radiation exceeded the dose normally associated with thyroid cancer or leukemia.[43] A recent study demonstrated that using a more restrictive protocol for obtaining CT imaging reduced the number of CT scans obtained in a cohort of trauma patients without increasing missed injuries or mortality.[44] With regard to using CT scanning in children, the pendulum is swinging back to the more restrictive use of CT scans, in order to avoid excessive amounts of radiation to younger patients, who have a higher lifetime risk of developing neoplasms after radiation.

CT is an accurate diagnostic tool and has become an integral component of the evaluation of injured patients. Although CT scans can be essential in the evaluation of many children, excessive use is discouraged because of the higher radiation exposure associated with CT scans, rare but important complications such as contrast reactions, and added costs. CT scans are a growing source of medical radiation exposure in children and may contribute to the occurrence of radiation-related malignancy, particularly when performed among younger children.[45]

The two most common body regions imaged with a CT scan in pediatric trauma are the head and abdomen/pelvis. A noncontrast head CT is performed to assess for closed head injuries and fractures that may require additional treatment such as a depressed skull fracture. The most common indication for a head CT scan after pediatric injury is a history of loss of consciousness or altered mental status. A head CT scan may also be necessary for preverbal children whose injury was not observed or those who have received endotracheal intubation or are sedated as they cannot be reliably assessed for a potential head injury.[46-48] A large multicenter trial derived and validated predictive rules to identify children at very low risk of clinically important traumatic brain injury after blunt trauma where a head CT scan may be unnecessary. These prediction rules had a sensitivity of 100% in children 2 years old and younger and 96.8% in children older than 2; negative predictive value was 100% for all ages (Fig. 118.6).[49]

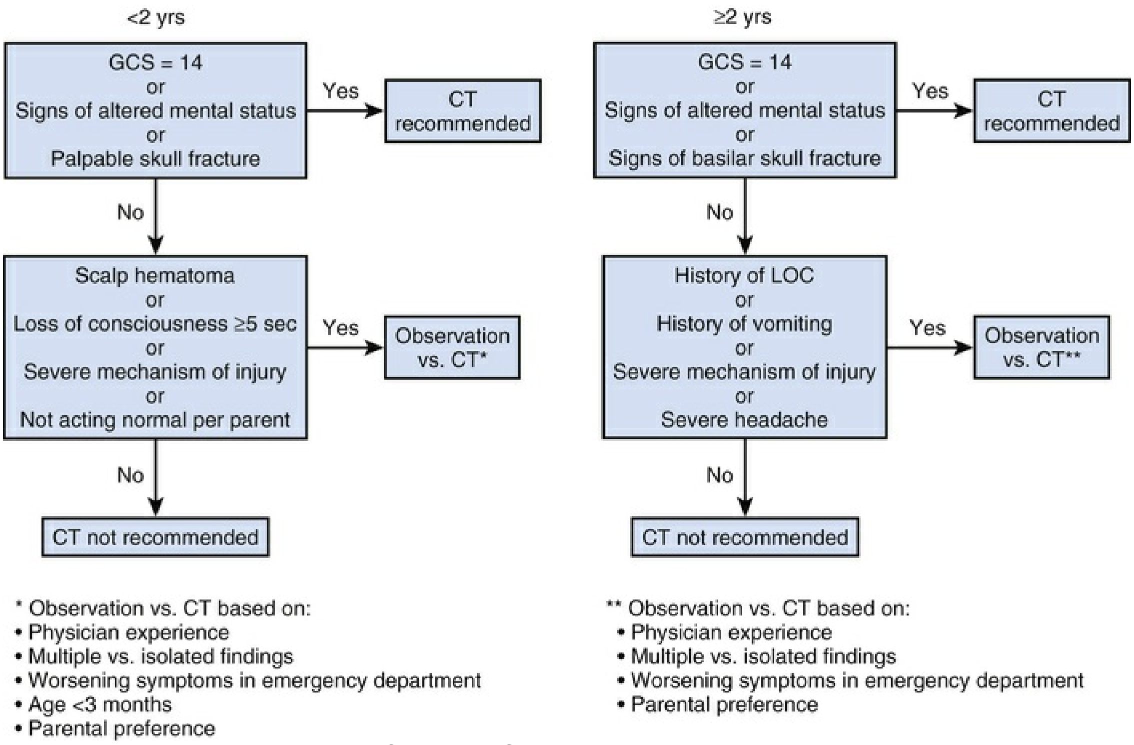

FIG. 118.6 Algorithm for head CT using predictive rules. (Modified from Kupperman N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study. Lancet. 2009;374:1160-1170.)

Recent emphasis on developing approaches to reduce the need for screening abdominal/pelvic CT scans in pediatric trauma continues to evolve. Imaging is indicated when an injury is suggested by physical examination findings such as major abdominal wall ecchymoses or abdominal tenderness. Among children who sustain a significant blunt injury but do not have physical examination findings suggesting an abdominal injury, the yield of screening abdominal CT scans is low. Screening laboratory tests, however, can be used to reduce unneeded imaging for these children.

While focused abdominal sonogram for trauma (FAST) has been widely adopted as a diagnostic tool for adult trauma patients, its value in pediatric trauma is less certain. FAST is focused on identifying fluid in four areas, the presence of which is suggestive of hemopericardium or intraabdominal injury: the pericardial sac, hepatorenal fossa, splenorenal fossa, and pouch of Douglas. Current evidence suggests that the role of FAST for evaluating children after blunt abdominal injury is limited. When used in children, FAST has only modest sensitivity (80%) for the detection of hemoperitoneum, and a negative ultrasound has questionable utility as the only test to exclude an intraabdominal injury.[50] Recent studies have suggested that FAST may be combined with screening laboratory studies to increase sensitivity, specificity, positive predictive value, and negative predictive value.[51]

Emergency Department Thoracotomy

Emergency department thoracotomy can be a lifesaving intervention among some children presenting in extremis after injury. This procedure, however, should be used selectively because its effectiveness has been shown to be limited to specific

patient subsets, including those who have received a brief period of cardiopulmonary resuscitation after sustaining a blunt injury or witnessed penetrating injury. Patients who sustain a penetrating injury are more likely to benefit from an emergency department thoracotomy because the higher potential for identifying injuries that can be treated after a thoracotomy has been performed. Data defining the role of emergency department thoracotomy in children are limited to small patient series and retrospective reviews. Available evidence suggests that this procedure should be reserved for pediatric patients who present with detectable vital signs and deteriorate despite maximal resuscitation.[52-55] Each institution should establish guidelines for the use of emergency department thoracotomy to aid in decision making when this rare procedure needs to be performed.

Emergency department thoracotomy should only be performed by a surgeon with appropriate training in this technique. A left anterolateral thoracotomy incision is made extending from left of the sternum in the fifth intercostal space to the table. A large incision is necessary to aid visualization and therapeutic interventions. This incision may be extended across to the right side of the chest (clamshell incision) if needed. The next step is to control hemorrhage by digital compression, suture control, or clamping of bleeding blood vessels. A pericardiotomy is performed using a longitudinal incision to evacuate hemopericardium blood and inspect the heart for injuries. Open cardiac massage can be performed if necessary. Cross-clamping the descending thoracic aorta will stop blood loss below the diaphragm and allow cardiac filling to maintain cardiac and brain perfusion. The pulmonary hilum can be clamped or manually compressed to control bleeding from the lung and pulmonary vessels.

Stabilization and Definitive Care

Following the initial resuscitation, a plan for the next step in care is defined. Children can be discharged from the emergency department if no injuries requiring inpatient observation or management are identified and there is a low suspicion of injury based on the clinical evaluation and mechanism of injury. Other children may require inpatient admission to either the hospital ward or ICU depending on the injuries identified. Some children may have injuries that require immediate operative repair and need to be moved directly to the operating room. Transfer to a higher level of care facility after evaluation and stabilization may be necessary if injuries are identified that cannot be treated at the receiving hospital. One important caveat is that if the emergency department physician or pediatrician determines from the primary and secondary surveys that the child will not be able to be treated at the initial receiving facility, it is important to promptly call the next highest level of care and not waste time obtaining CT scans or other studies that will not be acted on at the receiving facility.[56]

Conclusions

Pediatric trauma care requires an efficient team-based approach from prehospital care until the time of discharge. Within current trauma systems, patient care is optimized for efficiency and outcomes when each team member has a defined role

and effective communication is established within the team. By understanding the prioritized sequence of ATLS, rapid recognition and treatment of life-threatening injuries will occur efficiently within the team and greatly improve the outcome of these injured patients. Pediatric critical care providers will continue to take an active role in the management of the most severely injured pediatric trauma patients. Pediatric critical care physicians proficient in emergent procedures and knowledgeable of resuscitative measures in trauma care will augment the multidisciplinary approach to pediatric trauma care.

CHAPTER 119

Severe Traumatic Brain Injury in Infants and Children

Patrick M. Kochanek, Michael J. Bell, Hülya Bayır, Travis C. Jackson, Jessica S. Wallisch, Michael J. Forbes, Randall Ruppel, P. David Adelson, Robert S.B. Clark

PEARLS

- Complete and rapid physiologic resuscitation is essential to the initial treatment of infants and children with severe traumatic brain injury.
- There are many age- and injury mechanism–related differences that could greatly impact optimized therapy and outcome in severe pediatric versus adult traumatic brain injury; however, the key factors in this regard have yet to be fully elucidated.
- Monitoring and control of intracranial hypertension should begin with first-tier therapies and progress to less established second-tier therapies in refractory cases.
- The choice of second-tier therapy is based in part on an in-depth knowledge of the physiologic derangements involved and the preferences and expertise of the treating team.
- Advanced neuromonitoring is providing additional insight into pathophysiology-guided treatment.
- Because pediatric patients with traumatic brain injury often sustain multiple insults, appropriate correction of physiologic derangements and complications in other organ systems is also important in creating an optimal environment for recovery.
- Optimized rehabilitation can facilitate recovery after severe traumatic brain injury, and a link is emerging between intensive care unit management and the early application of rehabilitation therapies.

The publication of pediatric traumatic brain injury (TBI) guidelines in 2003 and an updated document in 2012 has helped to crystallize therapy and generate interest in

research on optimal pediatric intensive care unit (PICU) management of infants and children with severe TBI.[1,2] Subsequent to these guidelines and the previous edition of this textbook, several single-center studies have contributed to improving evidence-based care of children with severe TBI, and this information is incorporated into this chapter. However, there has been only one recent multicenter randomized controlled trial (RCT) in pediatric TBI, and thus the evidence for treatment approaches remains insufficient, and considerable heterogeneity in treatment remains. A current large comparative effectiveness study in pediatric TBI, Approaches and Decisions in Acute Pediatric TBI (ADAPT), is an exciting initiative that could be extremely important for the field. But it has not yet provided new published evidence on treatment other than to confirm that despite general adherence to the guidelines, therapy is extremely heterogeneous across major PICU programs nationally and internationally.[3] This chapter presents a practical and contemporary approach to the management of patients with TBI based on several sources of information: (1) the pediatric guidelines, (2) new data from studies in children and adults with severe TBI, and (3) accepted principles of the physiology and pathophysiology of TBI.

This chapter focuses on severe TBI, specifically on management in the PICU. PICU management has progressed from exclusively supportive care to strategies attempting to (1) optimize substrate delivery and cerebral metabolism, (2) mitigate (wherever possible) the evolution of the secondary injury cascade of events set into motion from the primary damage, (3) minimize secondary insults that might worsen secondary damage and outcome, (4) prevent severe or intractable intracranial hypertension or herniation, and (5) initiate selected rehabilitation therapies. The field is moving into an era targeting a precision medicine approach to define specific pediatric TBI phenotypes (based on a number of factors) and craft specific monitoring and management plans to optimize outcome. The role of newer technologies and the differences between adults and children are highlighted.

Epidemiology

Traumatic brain injury remains a significant pediatric health problem, with an estimated incidence of 80 pediatric hospitalizations and 6 pediatric deaths per 100,000.[4] Pediatric TBI cases that are severe (Glasgow Coma Scale [GCS] score <8) contribute to 30% of all injury-related deaths in the United States.[5] Although children 5 to 15 years of age generally have favorable outcomes compared with adults, children aged 4 years or younger—particularly those younger than 2 years—have a worse outcome than older children and adults.[6] Abusive head trauma (AHT) is the leading cause of severe TBI in infants and is believed to be the key contributor to poor outcomes in this younger subgroup, although other factors may play a role.[7,8] Data also suggest that the rate of AHT has increased, likely related to economic forces.[9] Note that *AHT* is the preferred term for this condition (in preference to *shaken baby syndrome, inflicted childhood neurotrauma,* or *nonaccidental trauma,* among others) per the American Academy of Pediatrics and is thus used in this chapter.[10] Penetrating injuries such as gunshot wounds, although not as common as either motor vehicle accidents or AHT, also contribute significant morbidity and mortality in the pediatric population.[11]

Pathophysiology

Severe TBI involves a primary injury that includes direct and immediate disruption of brain parenchyma. However, not all of the effects of the primary injury are immediately apparent because damage also evolves over time and results from a cascade of biochemical, cellular, and molecular events involved in the evolution of the injury. Many of the aspects of the primary injury are immediate or irreversible, whereas others continue to evolve triggering a secondary injury cascade that can, in some cases, be mitigated. Delayed neuronal death from apoptosis and death from secondary axotomy are perfect examples of this phenomenon. Both of these processes are set into motion by the primary injury but become secondary injury processes that take time to develop (sometimes days) and thus may be able to be blunted.[12-14] Additional secondary injuries are also important and result from extracerebral and intracerebral insults (eg, hypotension, hypoxemia, fever, ischemia, and refractory intracranial hypertension) at the injury scene and in the PICU. Three basic categories of mechanisms involved in the evolution of damage after TBI can be defined (Fig. 119.1): those associated with (1) ischemia, excitotoxicity, energy failure, and resultant cell death cascades; (2) secondary cerebral swelling; and (3) axonal injury. A fourth process, inflammation, is superimposed on these mechanisms and contributes to both further injury and repair. A constellation of mediators of secondary damage and repair is involved within each category. The contribution of each mediator to outcome and the interplay among them remain poorly defined. The biochemical and molecular responses to severe TBI resulting from AHT often are unique and generally severe.[7,8,15]

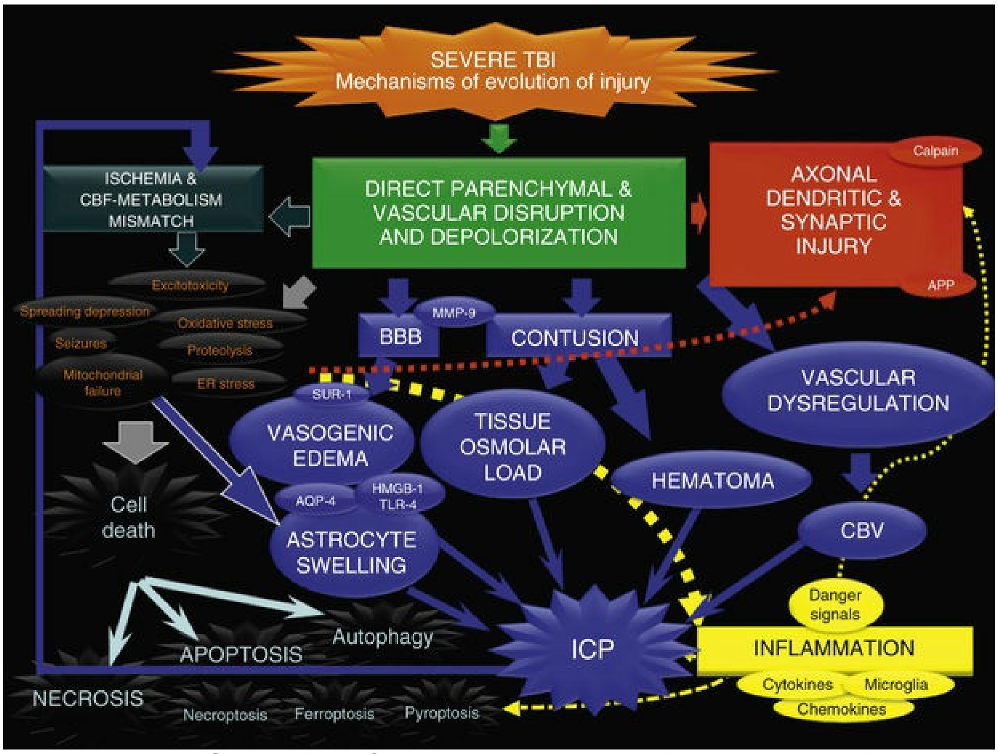

FIG. 119.1 Categories of mechanisms proposed to be involved in the evolution of secondary damage after severe traumatic brain injury (TBI) in infants and children. The major categories for these secondary

mechanisms are (1) ischemia, excitotoxicity, energy failure, and cell death cascades shown in black; (2) cerebral swelling shown in blue; (3) axonal injury shown in red; and (4) inflammation shown in yellow. Please see text for details. *APP,* amyloid precursor protein; *AQP-4,* aquaporin-4; *BBB,* blood-brain barrier; *CBV,* cerebral blood volume; *ER,* endoplasmic reticulum; *HMGB-1,* high-mobility group box 1 protein; *ICP,* intracranial pressure; *MMP-9,* matrix metalloproteinase-9; *SUR-1,* sulfonylurea receptor 1; *TLR-4,* toll-like receptor-4.

Posttraumatic Ischemia

The early studies of Pickels[16] and Bruce and associates[17] on cerebral blood flow (CBF) in pediatric TBI focused on the role of hyperemia in secondary brain swelling. However, Adelson and colleagues[18] assessed CBF in 30 infants and children after severe TBI. Early posttraumatic hypoperfusion was commonly observed, and a global CBF <20 mL/100 g/min was associated with a poor outcome. After the initial 24 hours, CBF often recovered, in some cases to high levels. However, delayed increases in CBF were not associated with poor outcome. This seminal finding shifted the emphasis toward the recognition and possible treatment of hypoperfusion early after TBI to avert secondary damage.

Numerous mechanisms may contribute to early posttraumatic hypoperfusion, including (1) direct vascular disruption; (2) an attenuated vasodilatory response to nitric oxide (NO), cyclic guanosine monophosphate, cyclic adenosine monophosphate, or prostanoids; (3) loss of endothelial NO production and elaboration of endothelin-1; and (4) production of other vasoconstrictor mediators.[19,20] Contemporary models suggest an important role of pericytes at the capillary level in the cerebral microcirculation.[21] Early after injury, increases in metabolic demands result from an uptake of glutamate and an increased risk from ischemic damage early after TBI.[22-24] Vavilala and coworkers[8] identified an important factor that could increase the importance of ischemic brain injury in infants and young children. They reported that no difference exists in the lower limit of blood pressure autoregulation of CBF in children younger than versus older than 2 years.[8] This finding led them to conclude that the autoregulatory reserve (ie, the difference between baseline mean arterial blood pressure [MAP] and the lower limit of autoregulation) is smaller in infants than in older children or adults; even modest MAP reductions may exacerbate ischemia in infants.

Excitotoxicity

Excitotoxicity is the process by which glutamate and other excitatory amino acids cause neuronal damage. Glutamate is the most abundant neurotransmitter in the brain, but exposure to toxic levels produces neuronal death.[25-28] Glutamate exposure produces neuronal injury by multiple mechanisms. Sodium-dependent neuronal swelling quickly occurs, followed by delayed, calcium-dependent degeneration. These effects are mediated through both ionophore-linked receptors, labeled according to specific agonists (*N*-methyl-D-aspartate [NMDA], kainite, and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), and receptors linked to second messenger systems (ie, metabotropic receptors). Activation of these receptors leads

to calcium accumulation via receptor-gated or voltage-gated channels or through the release of intracellular stores. Progress in NMDA receptor (NMDAR)-mediated neurotransmission has revealed greater complexity then previously appreciated—and may better inform therapy.[29] NMDARs consist of heterodimeric glutamate receptor (GluR) subunits including GluN1, GluN2A, and GluN2B. In adults, GluN2A-containing NMDARs are enriched in the synapse (synaptic NMDARs), whereas GluN2B-containing NMDARs are enriched at extrasynaptic sites (extrasynaptic NMDARs). During early development GluN2B will predominate the synapse. The special localization of NMDARs is believed to regulate activation of receptor-mediated cell death versus survival pathways. Activation of synaptic NMDARs is neuroprotective. They increase nuclear calcium, activate CREB, BDNF, protein kinase B (AKT), phosphorylated-JACOB (pJACOB), and upregulated antioxidants. In contrast, activation of extrasynaptic NMDARs by glutamate spillover or potentially malfunctioning astrocytes after injury has the opposite effect. Extrasynaptic NMDARs increase cytoplasmic calcium; inhibit CREB, AKT, p-JACOB, BDNF, and active calpain; stimulate death-associated protein kinase; and activate autophagy. Thus the extrasynaptic NMDARs may mediate neuronal death; also, glutamate toxicity may be especially catastrophic to the infant brain, which expresses high levels of numerous types of NMDAR subunits versus that in the adult. Pathologic increases in intracellular calcium concentration can also trigger other processes that can lead to cell death such as activation of constitutive NO synthase, leading to NO production, peroxynitrite formation, and resultant deoxyribonucleic acid (DNA) damage and poly(ADP-ribose) polymerase activation, which exacerbates adenosine triphosphate (ATP) depletion, metabolic failure, and necrotic cell death. Finally, evidence supports a role for the nonreceptor-mediated effects of high concentrations of glutamate in producing neuronal death.[30] Oxidative stress from intracellular glutathione depletion appears to play an important role.

In cerebrospinal fluid (CSF) from children with severe TBI, our group reported that glutamate levels were markedly increased[24] and correlated with both poor outcome and AHT as an injury mechanism.[24] Antiexcitotoxic therapies improve outcome after experimental TBI; pretreatment with NMDA antagonists (eg, MK-801) attenuate behavioral deficits.[31,32] Other therapies that modify glutamate-NMDA receptor interaction and improve outcome after experimental TBI are magnesium, glycine site antagonists, hypothermia, and pentobarbital. Despite this benefit, clinical trials with antiexcitotoxic therapies have been unsuccessful in adults, perhaps because of adverse effects of these drugs, delayed treatment, a relative reduction in NMDAR subunit targets, or the antiexcitotoxic effects of many current therapies (eg, barbiturates, hypothermia, and sedatives).[33] Developing neurons are more susceptible to excitotoxic injury than are mature cells; however, concerns have been raised about use of NMDA antagonists in infants because these drugs may induce apoptotic neurodegeneration.[34] Investigating which specific NMDA receptor subunits may need to be targeted to produce antiexcitotoxic effects without triggering apoptosis is a key area for future research in pediatric TBI. One agent that is seeing increased clinical use that has antiexcitotoxic properties is levetiracetam. A number of preclinical reports support its use and indicate that it is more neuroprotective that other anticonvulsants such as phenytoin.[32,35] However, an RCT testing levetiracetam in severe TBI has not been carried out in children, although a phase II study in children has been carried out and reported safety.[36]

Delayed Neuronal Death Cascades

Cells that die after TBI can be categorized on a morphologic continuum ranging from necrosis to apoptosis.[37,38] Apoptosis is a morphologic description of cell death defined by cell shrinkage and nuclear condensation, internucleosomal DNA fragmentation, and formation of apoptotic bodies.[39] In contrast, cells that die of necrosis display cellular and nuclear swelling with dissolution of membranes. Because apoptosis requires a cascade of intracellular events for completion of cell death, *programmed cell death* has also been used to describe this process. In diseases with complex and multiple mechanisms, such as TBI, distinguishing morphologic apoptotic from necrotic cell death as classically defined may be difficult,[40] and some cells have mixed phenotypes. In mature tissues, programmed cell death requires initiation via either intracellular or extracellular signals (Fig. 119.2). Intracellular signaling appears to be initiated in mitochondria, triggered by disturbances in cellular homeostasis such as ATP depletion, oxidative stress, or calcium fluxes.[41] Mitochondrial dysfunction leads to egress of cytochrome c into the cytosol. Oxidation of the mitochondrial lipid cardiolipin may play a central role in cytochrome c release.[42] Cytochrome c release can be blocked by antiapoptotic members of the Bcl-2 family (eg, Bcl-2, Bcl-xL, Bcl-w, and Mcl-1) and promoted by proapoptotic members of the Bcl-2 family (eg, Bax, Bcl-xS, Bad, and Bid).[43] Cytochrome c activates the initiator cysteine protease caspase-9.[44] Caspase-9 then activates the effector cysteine protease caspase-3, which cleaves cytoskeletal proteins, DNA repair proteins, and activators of endonucleases.[45] Intrinsic signaling of apoptosis can also proceed via mitochondrial release of apoptosis-inducing factor, a caspase-independent apoptotic process mediated by poly(ADP-ribose) polymerases and posttranslational poly-ADP-ribosylation (PAR) of proteins. As such, this apoptotic pathway is sometimes referred to as *parthanosis*.[46]

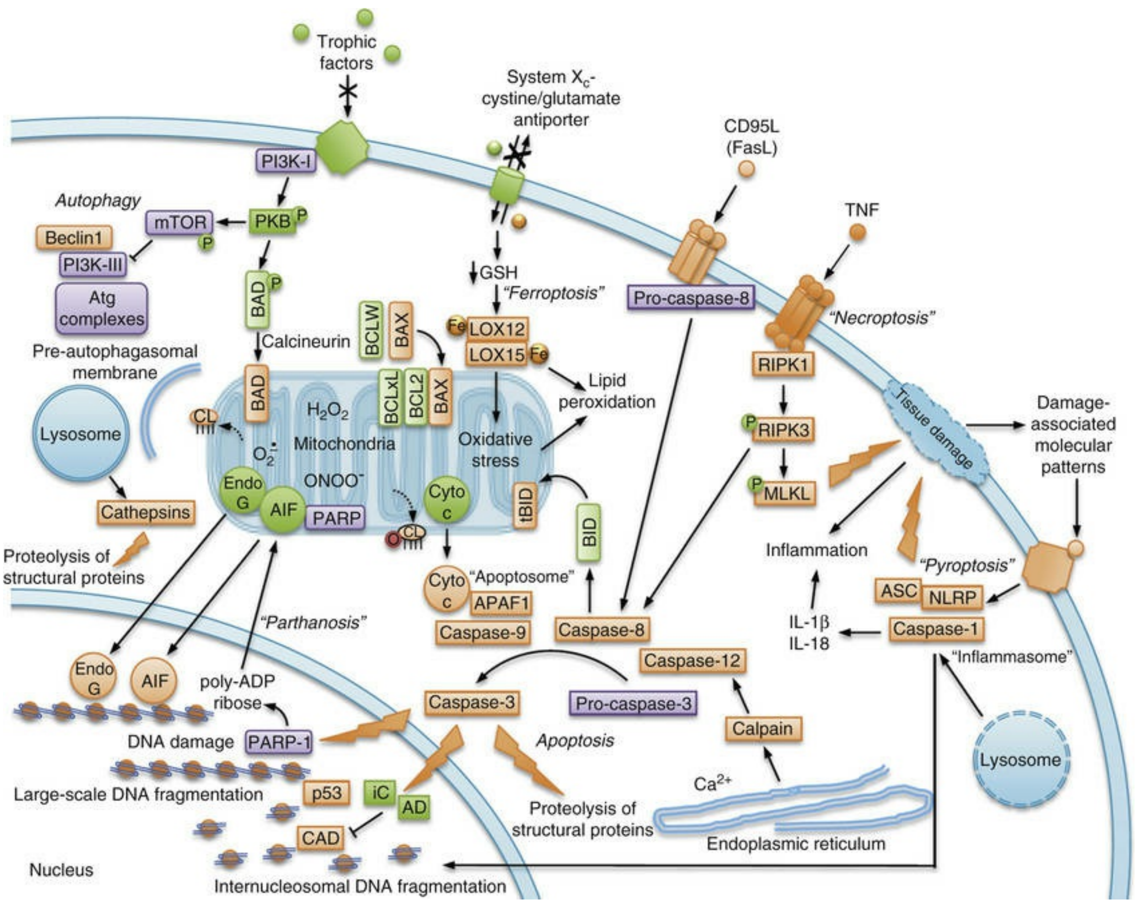

FIG. 119.2 Programmed apoptotic and regulated necrotic cell death cascades involved in delayed neuronal death after severe traumatic brain injury. *AIF,* apoptosis-inducing factor; *APAF,* apoptotic protease activating factor; *ASC,* caspase activity and recruitment domain; *Atg,* autophagy-related; *CAD,* caspase activated deoxyribonuclease; *CD95,* cluster of differentiation 95; *CL,* cardiolipin; *Cyto C,* cytochrome c; *DNA,* deoxyribonucleic acid; *EndoG,* endonuclease G; *Fe,* iron containing; *GSH,* glutathione; *iCAD,* inhibitor of CAD; *IL,* interleukin; *LOX,* lipoxygenase; *MLKL,* mixed lineage kinase domain-like; *mTOR,* mammalian target of rapamycin; *NLRP,* NOD-like receptor family, pyrin domain; *O,* oxidized; *P,* phosphorylated; *PARP,* poly(ADP-ribose) polymerase; *PI3K,* phosphoinositide 3-kinase; *PKB,* protein kinase B; *RIPK,* receptor-interacting protein kinase; *t,* truncated; *TNF,* tumor necrosis factor.

Extracellular signaling of apoptosis occurs via the tumor necrosis factor (TNF) superfamily of cell surface death receptors, which includes TNFR-1 and Fas/Apo1/CD95.[47] Receptor-ligand binding of tumor necrosis factor receptor 1 (TNFR-1)–TNF-α or Fas-FasL promotes formation of a trimeric complex of TNF- or Fas-associated death domains. These ultimately lead to caspase-3 activation, where the mitochondrial and cell death receptor pathways converge (see Fig. 119.2). Both the intrinsic and extrinsic pathways may contribute to the evolution of cell death after severe TBI in infants and children. CSF levels of the antiapoptotic protein Bcl-2 in pediatric patients after TBI were increased about fourfold in patients with TBI versus controls.[48] Similarly, CSF levels of sFas receptor and sFas ligand are increased in patients with TBI versus controls.[49] Apoptosis may be an important therapeutic

target for new therapies in infants with severe TBI. Current therapies likely attenuate both necrotic and apoptotic injury cascades.

Several additional cell death cascades have been shown to play a role in the evolution of neuronal death after TBI in preclinical models including pyroptosis, necroptosis, autophagy, and ferroptosis. Pyroptosis is an inflammasome-mediated cell death pathway linked to caspase-1 activation, IL1-β production, and mitochondrial pore formation,[50] whereas necroptosis represents TNF-triggered, receptor interacting protein kinases (RIPKs) and pseudokinase mixed lineage kinase domain-like (MLKL)-mediated programmed necrosis.[46] Autophagy involves phagocytosis of mitochondria and organelles in the setting of cellular injury—which may contribute to neuronal death or have beneficial properties.[51] Ferroptosis, an iron-dependent form of regulated necrosis, may also play a role.[52] All of these processes could represent targets for future therapies in TBI (see Fig. 119.1). Neuronal death after TBI may also result from disconnection with subsequent Wallerian degeneration of otherwise lethally injured axons. This aspect is discussed further in the section on axonal injury.

The currently available data strongly suggest that early after injury, severe TBI produces a state of hypoperfusion and loss of blood flow autoregulation with simultaneous increased metabolic demands from excitotoxicity. This is a state of enhanced vulnerability to secondary insults (ie, hypotension and hypoxemia). These processes are intimately linked with the evolution of neuronal death.

Cerebral Swelling

After the initial minutes to hours of posttraumatic hypoperfusion and hypermetabolism, a phase of metabolic depression occurs. The cerebral metabolic rate of oxygen ($CMRO_2$) decreases to about one-third of normal[53] and is maintained at that level for the duration of the coma, unless perturbed by second insults such as seizures or spreading depression.[54] The exact etiology of this state remains to be defined; however, contributions from reduced synaptic activity and mitochondrial failure may be important.[55] Sustained increases in glycolysis are reported in some cases, possibly related to seizure activity or sustained increases in glutamate levels.[22] Cerebral swelling develops and generally peaks between 24 and 72 hours after injury, although sustained increases in intracranial pressure (ICP) for 1 week or longer occasionally are observed.

Cerebral Blood Volume

Several mechanisms may contribute to intracranial hypertension in infants and children after severe TBI (see Fig. 119.1). Brain swelling and accompanying intracranial hypertension contribute to secondary damage in two ways. Intracranial hypertension can compromise cerebral perfusion leading to secondary ischemia, and it can produce the devastating consequences of deformation through herniation syndromes. Bruce and colleagues[17] described the phenomenon of "malignant posttraumatic cerebral swelling" in children. CBF was measured in six children, and hyperemia was believed to be the major culprit. Muizelaar and coworkers,[56] in a series of 32 children, suggested similar findings. However, Sharples and associates[57] suggested that hyperemia was uncommon after severe TBI in children; rather,

reduced $CMRO_2$ was associated with poor outcome. Suzuki[58] measured CBF in 80 normal children. He showed an age dependence of CBF, with high values in children ages 2 to 9 years, levels previously suggested to represent posttraumatic hyperemia. Nevertheless, in some patients with TBI, after resolution of the aforementioned early posttraumatic hypoperfusion, CBF may increase to levels greater than metabolic demands producing a state of relative hyperemia.[14]

Bergsneider and coworkers[23] posed the alternative hypothesis of *hyperglycolysis* to explain the increases in CBF in patients with severe TBI whose CBF is uncoupled from $CMRO_2$. Cerebral glutamate uptake is coupled to glucose utilization by glycolysis in astrocytes. Studies suggest two other potential contributors to increased glycolysis after TBI even in the absence of low CBF, namely mitochondrial failure[55] and nitration and inactivation of the enzyme pyruvate dehydrogenase, which is critical to the production of acetyl-CoA and thus oxidative metabolism.[59] Thus in injured brain regions with reduced $CMRO_2$, increases in CBF may be coupled to local increases in glucose utilization even in the absence of ischemia.

Local or global increases in glycolysis occur in adults with severe TBI.[23] The incidence or importance of secondary *hyperemia* or hyperglycolysis in pediatric TBI remains to be determined. It may occur in select cases, but secondary increases in CBF probably are not the major contributor to raised ICP. Increases in CBF were not associated with raised ICP in adults,[60] and hyperemia was not associated with poor outcome in children.[18] The contribution of hyperemia (increased cerebral blood volume [CBV]) to the development of raised ICP has been studied in adults with TBI.[60] Increased CBV was seen in only a small number of patients. These studies suggest that the importance of posttraumatic hyperemia was likely overstated, and edema rather than hyperemia may be the predominant contributor to brain swelling after TBI.[61] Loss of blood pressure autoregulation of CBF may also play a role in some patients by contributing to the development of intracranial hypertension. Studies using a pressure reactivity index (PRx) approach to assess the status of autoregulation at the bedside are shedding additional light on this possibility, and in some patients this tool may help define an optimal cerebral perfusion pressure (CPP), which may need to be individually targeted.[62,63]

Edema

Both cytotoxic and vasogenic edema may play important roles in cerebral swelling (Fig. 119.3). However, the traditional concept of cytotoxic and vasogenic edema is evolving. There appear to be multiple mechanisms for edema formation in the injured brain. First, vasogenic edema may form in the extracellular space as a result of blood-brain barrier (BBB) disruption. Second, cellular swelling can be produced in two ways. Astrocyte swelling can occur as part of the homeostatic uptake of substances such as glutamate. Glutamate uptake is coupled to glucose utilization via a sodium/potassium adenosine triphosphatase, with sodium and water accumulation in astrocytes. Swelling of both neurons and other cells in the neuropil can result from ischemia- or trauma-induced ionic pump failure. Finally, osmolar swelling may contribute to edema formation in the extracellular space, particularly in contusions. Osmolar swelling actually is dependent on an intact BBB or an alternative solute barrier. Cellular swelling may be of greatest importance. Using a model of diffuse TBI in rats, Barzo and coworkers[64] applied diffusion-weighted

magnetic resonance imaging to localize the increase in brain water. A decrease in the apparent diffuse coefficient after injury suggested largely cellular swelling rather than vasogenic edema in the development of raised ICP. Katayama and associates[65] also suggested that the role of BBB in the development of posttraumatic edema may have been overstated, even in the setting of cerebral contusion. They posed that as macromolecules are degraded within injured brain regions, the osmolar load in the contused tissue increases. As the BBB reconstitutes (or as other osmolar barriers form), a large osmolar driving force for local accumulation of water develops, resulting in the marked swelling so often seen in and around cerebral contusions. Thus in either diffuse injury or focal contusion, BBB permeability may play a limited role in the development of cerebral swelling. If these results can be generalized, then hypertonic saline solution or mannitol would represent optimal therapies particularly outside of the immediate postinjury time period. However, a role for BBB permeability in cases of severe TBI should not be dismissed. Polderman and colleagues[66] reported that prolonged use (>48 hours) of mannitol (a large molecule that does not cross the intact BBB) was associated with its progressive accumulation in CSF in adults with severe TBI, and in some cases, a reverse osmotic gradient was even established. This suggests that breaching of the BBB is important and that prolonged use of osmolar therapy might, in some patients, produce rebound intracranial hypertension. Studies of the extent of BBB injury versus the contribution of cellular swelling to intracranial hypertension in pediatric TBI are needed.

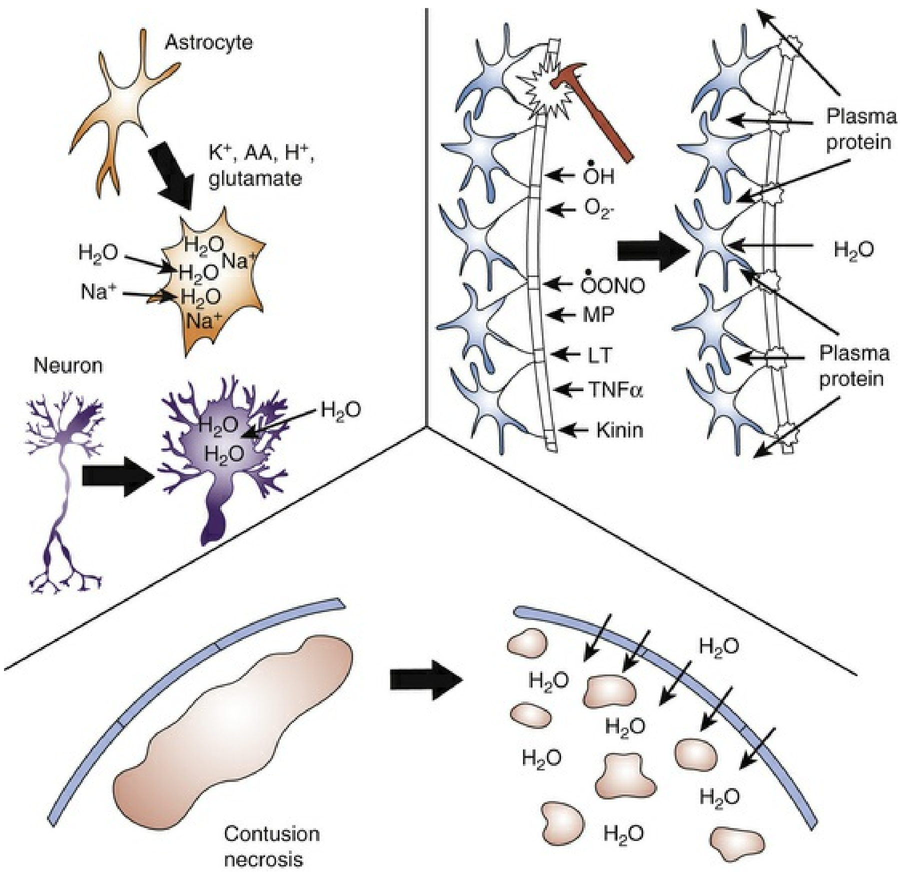

FIG. 119.3 Schematic of three classic cascades leading to cerebral edema. *Top left,* Cellular swelling is predominantly seen in astrocytes and is stimulated by potassium, acidosis, glutamate, arachidonic acid (AA),

and other factors. This key pathway is less representative of a toxic process and more consistent with a homeostatic or mediator-driven process. Neuronal swelling from pump leak probably is less important. *Bottom,* Osmolar swelling from contusion necrosis. In the hours after injury, reconstitution of the BBB or development of an osmolar barrier around a contusion sets the stage for marked local swelling as macromolecules in the contusion break down, increasing local osmolality. *Top right,* Vasogenic edema results from protein and water accumulation across the damaged BBB, which is formed by tight junctions (astrocyte foot processes). Direct vascular disruption by trauma, reactive oxygen species such as hydroxyl radical (OH), superoxide anion (O_2–), and peroxynitrite (ONOO), metalloproteases (MP), kinins, leukotrienes (LT), cytokines, and other mediators contribute to BBB damage. *TNF,* tumor necrosis factor.

There have been a number of exciting new developments in our understanding of the development of brain edema based on new pathways that may represent therapeutic targets (also see Fig. 119.4).[29] This includes sulfonylurea receptor 1 (Sur-1)-regulated cation channels, which can be targeted by the drug glyburide[67]; aquaporin-4 channels, which can be blocked either with direct channel blockers or via inhibition of their upregulation,[68] which may be linked to high-mobility group box 1 (HMGB-1) release or toll-receptor activation[69]; and the use of novel resuscitation agents to reduce fluid requirements.[70] These are promising developments that are already generating clinical trials in adults (glyburide (RP-1127) for TBI; NCT01454154).

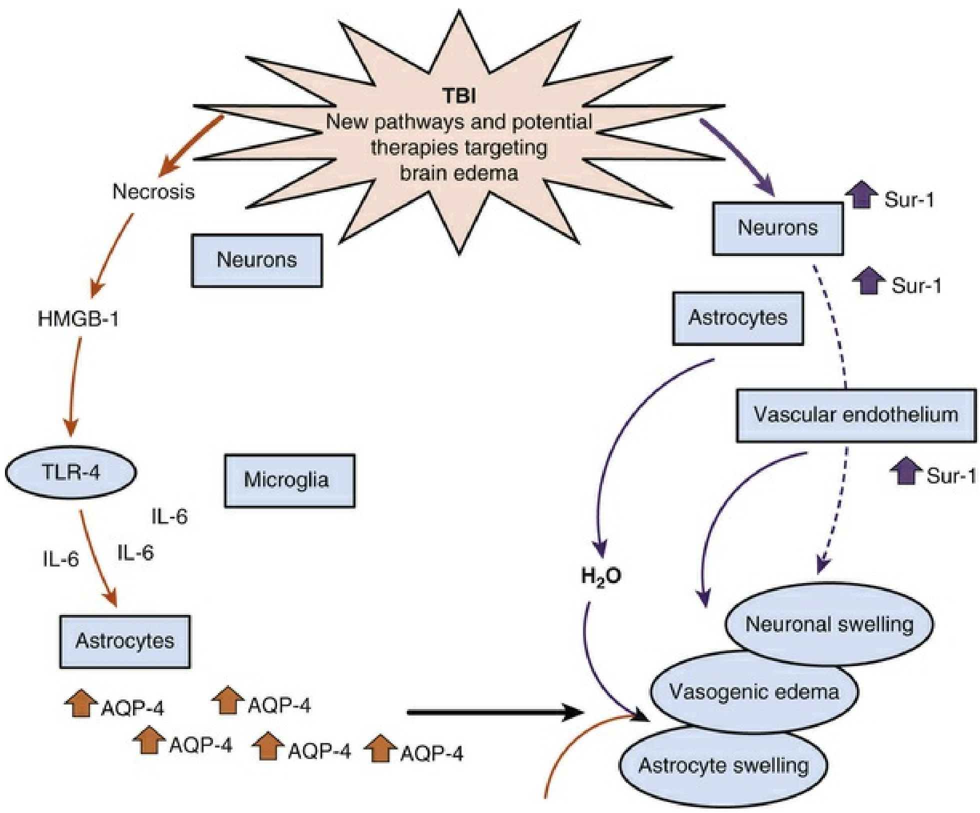

FIG. 119.4 State-of-the-art view of novel molecular participants in the development of cerebral edema after traumatic brain injury (TBI). On the

left, neuronal necrosis results in release of the high-mobility group box 1 protein (HMGB-1), which binds to toll-like receptor-4 (TLR-4) on microglia leading to interleukin-6 (IL-6) production and upregulation of AQP-4 water channels as suggested by Laird and colleagues.[69] On the right, upregulation of sulfonylurea receptor-1 (SUR-1) leads to ion channel opening and water accumulation.[70]

Axonal Injury

Traumatic axonal injury (TAI) encompasses the spectrum from mild to severe TBI.[71,72] The extent and distribution of TAI depend on injury severity and category (focal versus diffuse). Its incidence and nature appear to be age independent,[73] but its consequences may be particularly devastating in children.[74] The effects of TAI in children during a period of developmental axonal connectivity remain unknown but likely are considerable. Clinical data on TAI after pediatric TBI are limited. However, strongly supporting the role for TAI in pediatric TBI, after publication of the guidelines, Berger and colleagues[75] reported that serum levels of myelin basic protein are markedly increased in infants and children after either accidental TBI or AHT—in contrast to hypoxic-ischemic encephalopathy. Massive increases in CSF levels of myelin basic protein were also reported after severe TBI in children.[76] In children affected by AHT, TAI may be highly prevalent.[77] The classic view suggested that TAI occurs because immediate physical shearing with frank axonal tears occurs. Experimental studies, however, suggest that TAI occurs by a delayed process termed *secondary axotomy,* which results from either calcium accumulation or altered axoplasmic flow with accumulation of proteins such as amyloid precursor protein (APP) (Fig. 119.5).[78] What remains to be determined is how much of TAI results from a reversible evolution of damage to axons versus Wallerian degeneration of disconnected axons. The former but not the latter would be amenable to treatment. Studies also have shown that there are as many if not more unmyelinated than myelinated axons that are injured after TBI.[79] Laboratory studies suggest that hypothermia, calpain antagonists, and cyclosporine A can attenuate TAI, but clinical data are lacking.

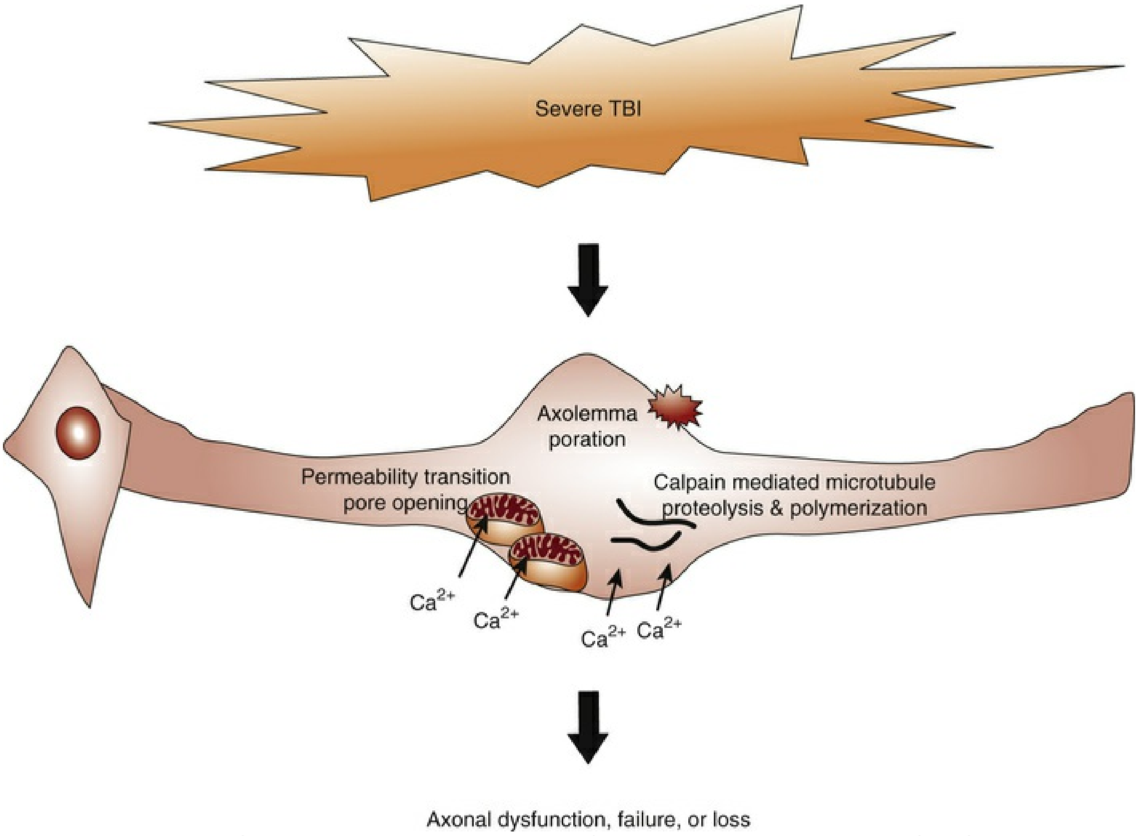

FIG. 119.5 Secondary injury cascade after traumatic brain injury (TBI) relevant specifically to traumatic axonal injury. Rather than direct axonal disruption from trauma, shearing forces set into motion several processes including mitochondrial permeability transition pore opening and resultant mitochondrial failure and calpain-mediated proteolysis of microtubules, both of which lead to failure of axoplasmic transport and accumulation of proteins such as amyloid precursor protein. In addition, direct axolemmal poration may occur.

History

Unlike in adult TBI, where the history is generally straightforward, the special case of AHT contributes to increased importance of the history in pediatric TBI. For a discussion of the topic, the reader is referred to Duhaime.[80] In cases of severe AHT, a history that is incompatible with the observed injury is often given.[81] Occult presentations of AHT can be particularly important because they may be recognized as cases of severe TBI relatively late in their treatment course.[82] In this setting, brain edema already may have evolved to life-threatening levels, and other superimposed secondary insults (eg, seizures and apnea) may complicate management and worsen outcome.

Signs and Symptoms

The GCS score[83] (Table 119.1), first described in 1974, remains a valuable tool for grading and communicating severity of neurologic injury after TBI, although limitations remain with pediatric use. The verbal and motor components of the GCS

score have been modified for the assessment of infants,[84] but this modification has not been validated. The motor score has probably become the most important component of the GCS. A rapid *mini-neuroassessment* that allows evaluation of the patient's level of consciousness, pupillary size and light response, the fundi, extraocular movements, response of extremities to pain, deep tendon reflexes, and brain stem reflexes should all be part of the initial evaluation.[85] Until proved otherwise, an altered level of consciousness, pupillary dysfunction, and lateralizing extremity weakness in an infant or child should raise suspicion of a mass lesion that may require surgery.[86] These signs of impending herniation require an immediate response, as outlined in Fig. 119.6.

TABLE 119.1
Coma Scales

Glasgow Coma Scale	Modified Coma Scale	Point Scale
Eye Opening

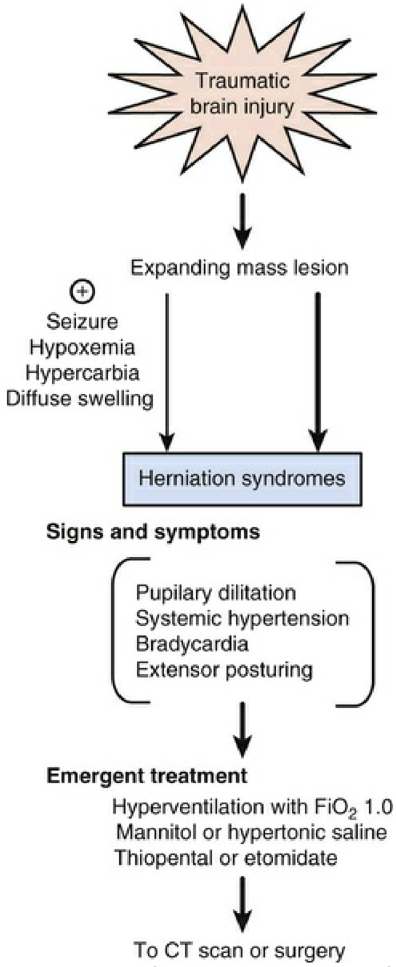

FIG. 119.6 Treatment paradigm for management of signs and symptoms of acute herniation after severe traumatic brain injury in infants and children.

Initial Resuscitation

The identification and correction of airway obstruction, inadequate ventilation, and shock take priority over a detailed neurologic assessment.[87] Thus the first step in managing a patient with TBI is complete, rapid physiologic resuscitation.[1,2] Raised ICP and cerebral herniation are the major complications. Brain-specific interventions in the absence of signs of herniation or other neurologic deterioration currently are not recommended. Mannitol may be counterproductive for the management of malignant intracranial hypertension during initial resuscitative efforts, and some have suggested that immediate post-TBI use of either osmolar agents or colloids could cause leakage into the injured brain and contribute to the development of a reverse osmolar gradient and delayed swelling.[88,89] Studies have consistently shown that increased morbidity and mortality are associated with the secondary insults of hypotension and hypoxemia.[90] Gentleman[91] reported that the increased use of tracheal intubation and ventilation produced a concomitant reduction in hypoxemia and an increase in favorable outcomes. Although the basis for this improvement may be multifactorial, early correction of hypoxemia and hypovolemia must be the initial objective. However, specific recommendations for intubation at the scene are

complex and likely are influenced by the expertise of caregivers in the field and by the transport distance, among other factors.[92]

Trauma patients with supraclavicular injury should be assumed to have cranial and cervical spine injuries until proved otherwise. The initial evaluation of a child after severe TBI begins by demonstrating the presence of a patent, maintainable airway; the patient must be conscious, alert, and breathing spontaneously. Unconscious patients must be assumed to have an obstructed airway requiring immediate evaluation. The relatively large head, occiput, and tongue and the short narrow epiglottis of the infant facilitate airway obstruction if the child's sensorium has been clouded. The rescuer must alleviate this situation (while protecting the cervical spine) to minimize secondary injury from hypoxia.

When preparing to intubate an infant or child with severe TBI, it is important to have readily available suction and age-appropriate suction catheters. Optimal positioning of the patient requires immobilization of the neck to stabilize the cervical spine. A fraction of inspired oxygen [F_{IO_2}] of 1.0 should be delivered by facemask immediately before intubation to facilitate nitrogen washout from the functional residual capacity and maximize alveolar oxygenation. An age-appropriate laryngoscope blade and tracheal tube are then selected. The medications chosen must be potent and rapid in their onset of action. The goals of analgesia, amnesia, and neuromuscular blockade must be met rapidly. Ideally, the patient never receives a preintubation positive pressure breath. Tracheal intubation of the child with severe TBI requires a cerebroprotective, rapid-sequence technique when possible. Bag-valve-mask positive pressure ventilation should be avoided. However, in cases of hypoxemia or impending herniation, positive pressure ventilation should be instituted immediately.[93] Because the bag-valve-mask technique may cause unintentional cervical spine manipulation, care is advised.[94] The tube is secured with adhesive tape that should not pass circumferentially around the neck because cerebral venous return may be reduced.

If a person who has sustained TBI meets any of the criteria listed in Box 119.1, assisted ventilation is generally indicated.[93,95] In children, the recommended route of initial airway control is orotracheal intubation under direct vision.[96] Nasotracheal intubation should be avoided. Orotracheal intubation can be accomplished using a two-person strategy that protects the cervical spine from injury. A normal lateral cervical spine roentgenogram is reassuring but does not rule out cervical spine injury.[97] Spinal immobilization must be maintained,[98] which is accomplished via in-line cervical immobilization by one operator while the second intubates the trachea. Care must be taken to avoid pressing into the soft tissues of the submental region and strap muscles because inadvertent airway obstruction may ensue.

Box 119.1

Criteria for Intubation of the Head-Injured Child

Glasgow Coma Scale (GCS) score ≤10

Decrease in GCS of >3, independent of the initial GCS score

Anisocoria >1 mm

Cervical spine injury compromising ventilation

Apnea

Hypercarbia ($Paco_2$ >45 mm Hg)

Loss of pharyngeal reflex

Spontaneous hyperventilation causing Paco2 <25 mm Hg

Rapid-Sequence Induction and Intubation

Tracheal intubation, although lifesaving, is a noxious stimulus. The technique of rapid-sequence induction and intubation secures the airway of an unprepared patient, who is at risk for aspiration of gastric contents, in an immediate and safe manner. No resistance is provided to direct laryngoscopy, and the normal responses to intentional placement of a foreign body into the trachea are eliminated. Rapid-sequence induction is documented to be a safer technique than either nasotracheal intubation or orotracheal intubation without neuromuscular blockade.[99,100]

In the pediatric patient with TBI, a cerebroprotective rapid-sequence induction strategy should be used. The sequence involves preparation, preoxygenation, sedation, neuromuscular blockade, and orotracheal intubation. Pharmacologic adjuncts are used to prevent morbidity associated with hypotension, hypoxemia, intracranial hypertension, and gastric aspiration. The neurologic and hemodynamic status of the patient directs the choice of adjunctive pharmacologic strategy.

For a victim in cardiac arrest, cardiopulmonary resuscitation should begin immediately, accompanied by direct orotracheal intubation. No pharmacologic adjuncts are necessary to secure the airway. For a hemodynamically unstable patient, the combination of fentanyl, lidocaine, and rocuronium bromide is the first choice (Table 119.2). At Pittsburgh Children's Hospital either etomidate or fentanyl, in combination with lidocaine, is used for rapid sequence intubation. Etomidate use is accompanied by concerns with adrenal suppression.[101] Fentanyl, in combination with lidocaine, reduces the catecholamine surge associated with direct laryngoscopy.[93] Either of these same sequences of drugs can be used in hemodynamically stable patients, for whom a rapidly acting benzodiazepine (midazolam) can be added. Historically, thiopental was an excellent agent for rapid sequence induction in hemodynamically stable patients, but its availability has been curtailed related to its use in lethal injections in the United States. Alternatively, similar CNS effects can be achieved with propofol if there is no concern of hemodynamic compromise.

TABLE 119.2

Drugs for Intubation of the Head-Injured Child

Situation	Drugs
Cardiopulmonary arrest	Resuscitation drugs
Hemodynamically unstable	Fentanyl 2–4 μg/kg
	Lidocaine 1 mg/kg
	Rocuronium 1 mg/kg or vecuronium 0.3 mg/kg
Hemodynamically stable	Fentanyl 2–4 μg/kg or etomidate 0.1–0.3 mg/kg

	Lidocaine 1 mg/kg
	Midazolam 0.1–0.2 mg/kg
	Rocuronium 1 mg/kg or vecuronium 0.3 mg/kg

Circulatory Stabilization

Assessment of circulatory function after trauma involves the rapid determination of heart rate, blood pressure, central and peripheral pulse quality, capillary refill, and cerebral perfusion.[102] Posttraumatic hypoperfusion must be assumed to be hypovolemic (ie, hemorrhagic) in nature, but it also may have a secondary component of myocardial depression resulting from cardiac contusion. However, cardiac contusion is less common in children than in adults. In patients with severe TBI, fluid therapy for hypovolemic shock entails rapid replacement of vascular volume. The current recommendation is 20 mL/kg isotonic crystalloid (0.9% NaCl solution) given as soon as vascular access is obtained. Hypotonic fluid should not be used in the resuscitation of a patient with a brain injury. Subsequent doses of fluid should be isotonic crystalloid or packed red blood cells and titrated based on serial assessment of blood pressure, perfusion, and hematocrit. Although concerns exist regarding the relative hypotonicity of lactated Ringer solution,[103] evidence from studies in laboratory animals supports the safety of the use of lactated Ringer solution in patients with TBI.[104] Fisher and colleagues[105] reported the successful use of 3% saline solution as a maintenance fluid in children with TBI. Titration of 3% saline solution as an infusion to prevent development of intracranial hypertension is an acceptable first-tier strategy. Unfortunately, hypertonic saline, albumin, or other colloids have all failed to show efficacy in TBI resuscitation. Albumin use in acute ICU fluid management in adult TBI patients was associated with increased mortality, and National Institutes of Health (NIH)–funded trials in adults involving hypertonic saline (7.5%) with or without 6% dextran-70 were halted because of futility.[106,107] Details of the approach to osmotherapy are discussed later in this chapter.

Herniation

The need to simultaneously address airway control, cardiovascular assessment and stabilization, treatment of extracerebral insults (hemorrhage and multiple trauma), and initial trauma survey in the field and emergency department makes management challenging. Although mass lesions are less common in children than in adults, they still occur in about 30% of children with severe TBI. Some of these patients, particularly those with rapidly expanding mass lesions (eg, epidural hematoma), can present with signs and symptoms of herniation (ie, pupillary dilatation, systemic hypertension, bradycardia, and extensor posturing). Because the devastating complications of herniation can sometimes be successfully prevented or treated in the initial minutes of their progression, the importance of aggressively and presumptively treating signs and symptoms of herniation, which is a medical emergency, cannot be overemphasized until these signs and symptoms are proved not to represent herniation.

Appropriately, there has been a move away from prophylactic application of aggressive hyperventilation for the management of severe TBI. However, it is important to recognize that temporary use of hyperventilation with an F_{IO_2} of 1.0 is a

therapy that can be immediately applied and can be lifesaving in the setting of impending herniation until other therapies can be instituted. Intubating doses of etomidate, pentobarbital, or fentanyl and lidocaine and mannitol (0.25 to 1.0 g/kg) or hypertonic saline (3% or 23.4%) solution[105,108] also should be given emergently. One must recognize that factors other than a focal mass lesion may lead to herniation and that these situations may arise more commonly in children than in adults. Diffuse swelling is more common in children than in adults, and in this setting, inadvertent hypercarbia or hypoxemia, iatrogenic excessive fluid administration, or status epilepticus after TBI can precipitate herniation. Although discussed in this chapter in the context of acute therapy, herniation can occur at any time in the PICU course, and this approach to treatment also applies (see Fig. 119.6).

Transition From the Emergency Department to the Pediatric Intensive Care Unit: Computed Tomographic Scan and Intracranial Pressure Monitoring

The transition of patients with severe TBI from the emergency department to the PICU includes computed tomographic (CT) evaluation of the head (and other anatomic regions, when clinically indicated) followed by placement of an ICP monitor, transport to the operating suite for surgical intervention, or both. In the initial resuscitation, sedation must be carefully titrated, maintaining the difficult balance that produces stability, analgesia, and anxiolysis during transport and scanning while allowing for rapid emergence for clinical assessment (as indicated) until a decision is made regarding surgery or ICP monitoring. Because the early period after injury generally reflects a state of increased vulnerability of the brain to second insults because of the brain's increased metabolic demands and compromised perfusion, providing adequate sedation and maintaining stable hemodynamics are important. An end-tidal CO_2 monitor also should be considered to avoid iatrogenic hyperventilation or hypoventilation. Clinical trials supporting definitive recommendations are not available. Nevertheless, the risks of intrahospital transport are well described[109]; therefore when possible, a physician should accompany the infant or child upon transport to the scanner to direct care, because serial assessment to titrate therapy is needed during the acute phase of injury.

Diagnostic Studies and Monitoring Modalities

Computed Tomography

Since becoming commercially available in 1973, CT has been of enormous benefit to neurointensive care.[110] Examples of classic findings in severe pediatric TBI are shown in Fig. 119.7. Comprehensive classifications of CT findings in adults with severe TBI are reported. The Marshall classification is the most commonly used (Table 119.3).[111] A similar system specifically for pediatric TBI is not described, although several reviews characterize the spectrum of injury in infants and children as defined by CT.[112,113] Ewing-Cobbs and colleagues[112] compared acute CT findings in infants and children with AHT and accidental injuries. Subdural interhemispheric and convexity hemorrhages and preexisting lesions were two to three times more common in the

group with AHT. Epidural hematomas were more common in the group with accidental TBI.

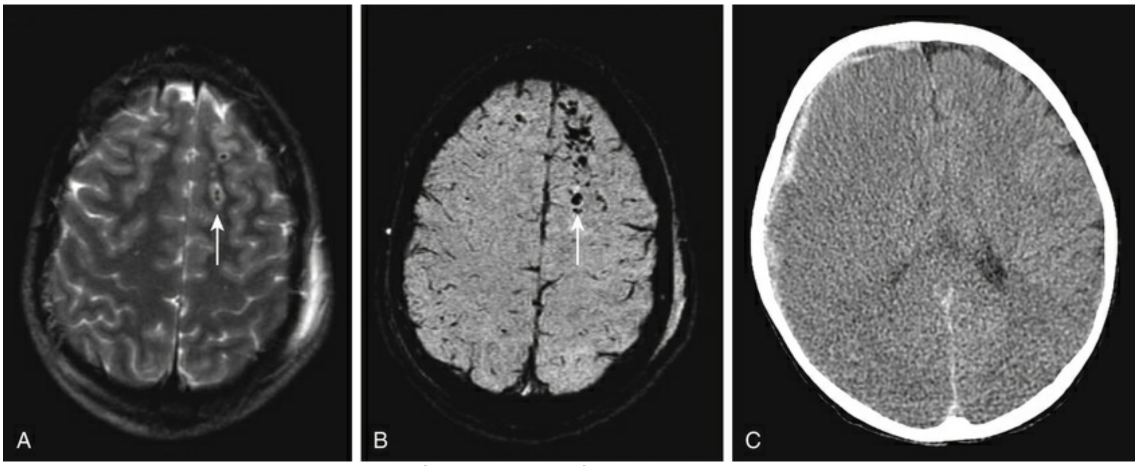

FIG. 119.7 Axial cranial CT images of important lesions in pediatric traumatic brain injury including (A) acute epidural hematoma, (B) penetrating brain injury resulting from a gunshot wound (with bullet fragments), and (C) abusive head trauma (shaken baby syndrome) with acute right subdural hematoma extending over most of the right hemisphere, right side alterations of gray-white differentiation, and decreased CSF spaces.

TABLE 119.3

Marshall Classification of Cranial Computed Tomographic Scans

Classification	Findings on Scan
Diffuse injury I (no visible pathologic change)	No visible intracranial pathologic change seen on computed tomography
Diffuse injury II	Cisterns are present with shift 0-5 mm or lesion densities present
	No high or mixed density lesion >25 mL
	May include bone fragments and foreign bodies
Diffuse injury III	Cisterns compressed or absent (swelling) with shift 0–5 mm
	No high or mixed density lesion >25 mL
Diffuse injury IV (shift)	Shift >5 mm
	No high or mixed density lesion >25 mL
Evacuated mass lesion	Any surgically evacuated lesion
Nonevacuated mass	High or mixed density lesion >25 mL, not surgically evacuated
Brain dead	No brain stem reflexes
	Flaccidity
	Fixed and nonreactive pupils
	No spontaneous respirations with a normal Pa_{CO_2}
	Spinal reflexes permitted

Timing of repeat cranial CT scans has been investigated in children. Routine reimaging at 24 or 48 hours after injury has been suggested.[114] However, Tabori and associates[115] evaluated the impact of routine reimaging on 67 children after severe TBI and noted that although some new lesions were identified, reimaging did not lead to surgical or medical changes in therapy in any patient. A decision to reimage based on changes in ICP or clinical examination was recommended. Such an approach also is recommended in the pediatric guidelines.[1,2]

Studies in adults and children indicate that CT scans are not without limitations

and must be used as only one, albeit important, piece of information. After severe TBI, in about 15% of adults with a normal CT scan, clinically significant intracranial hypertension develops. In contrast, in a study in 65 children, CT scans had a high false-positive rate in defining increased ICP.[116] Finally, patients with normal initial head CT scans who also have hypotension or abnormal posturing have the same propensity to the development of intracranial hypertension as do their counterparts with an abnormal scan.

Magnetic Resonance Imaging

MRI may have future applications salient to acute management in persons with TBI. The application of diffusion-weighted MRI for studying the evolution of cerebral edema,[60] the use of novel MRI methods for quantifying CBF,[117] and new methods such as susceptibility-weighted, diffusion tensor (Fig. 119.8) and state-of-the-art high definition fiber tract (Fig. 119.9) imaging to assess white matter damage increasingly are being applied.[118,119] The potential ability to couple these techniques with MR spectroscopy and functional MRI is beginning to yield unprecedented advances in our understanding of the brain's response to injury. However, MRI suites in most institutions are remote from the emergency department and PICU, introducing the risk of transport. Currently, hardware incompatibilities (eg, ventilators and intravenous pumps) and long data acquisition times (relative to CT) limit the utility of this important tool.

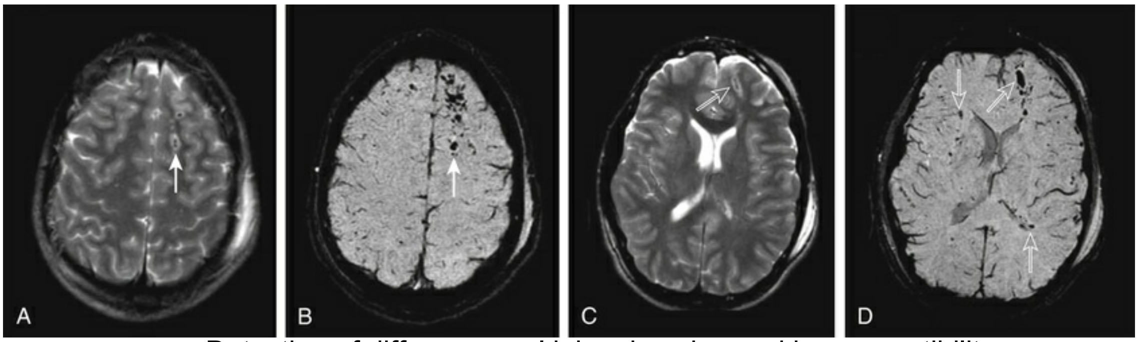

FIG. 119.8 Detection of diffuse axonal injury is enhanced by susceptibility-weighted magnetic resonance imaging (SWI). (A and C) Subtle hemorrhage in white matter is seen with conventional axial T_2-weighted imaging. (B and D) The diffuse white matter hemorrhages are much more readily detectible on SWI. The arrows in each example identify the hemorrhages. (From Tong KA, Ashwal S, Obenaus A, et al. Susceptibility-weighted MR imaging: a review of clinical applications in children. AJNR Am J Neuroradiol. 2008;29:9-17.)

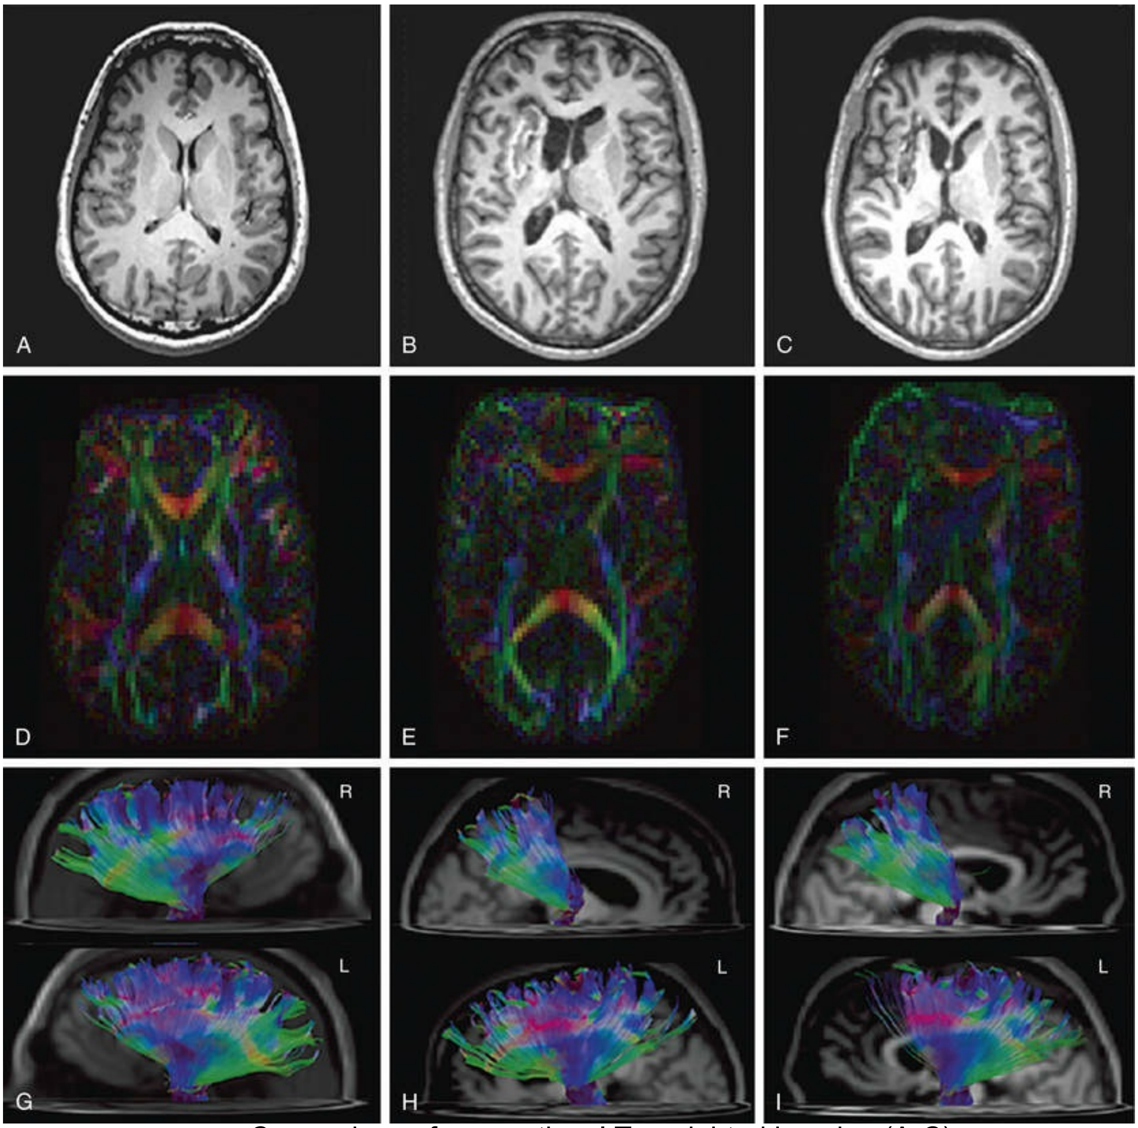

FIG. 119.9 Comparison of conventional T_1-weighted imaging (A-C), diffusion tensor imaging fractional anisotropy maps (D-F), and state-of-the-art high-definition fiber tract (HDFT) imaging (G-I) of a healthy volunteer (A, D, G) and a traumatic brain injury patient at 4 months (B, E, H) or 10 months (C, F, I) after injury. HDFT demonstrates the progression of loss of white matter tracts with remarkable anatomic clarity. (From Shin SS, Verstynen T, Pathak S, et al. High-definition fiber tracking for assessment of neurological deficit in a case of traumatic brain injury: finding, visualizing, and interpreting small sites of damage. J Neurosurg. 2012;116:1062-1069.)

Intracranial Pressure Monitoring

Unfortunately, clinical signs such as pupillary size, light response, and papilledema fail as early indicators of intracranial hypertension. Although the most reliable clinical signs are those associated with herniation, the introduction of ICP monitoring devices has allowed detection of intracranial hypertension well before herniation develops allowing us to target the impact of raised ICP on perfusion and possibly other mechanisms.[120,121] In the pediatric guidelines,[1,2] ICP monitoring was suggested as appropriate in children with an abnormal admission head CT scan and

initial GCS score between 3 and 8. Also, ICP monitoring was suggested to be appropriate in adults with severe TBI and a normal head CT scan if the clinical course was complicated by hypotension or motor posturing. This modality is essential to implementation of a physiologically guided approach to management of cerebral perfusion pressure (CPP) in the infant or child with severe TBI.[122]

ICP monitoring has not been studied in an RCT in children to establish its efficacy in altering outcome after severe TBI in either adults or children. Forsyth and coworkers[123] examined the United Kingdom multicenter database of more than 500 cases of pediatric TBI and reported that both ICP >20 mm Hg and lack of ICP monitoring were independently associated with death before discharge. Given that raised ICP correlates with poor outcome, there is a strong rationale for identifying and treating this problem.[124] As discussed in the section on CT, although CT is useful for identifying patients at high risk for the development of raised ICP (eg, those with mass lesions), the finding of a "normal" cranial CT scan does not rule out the potential for raised ICP.[125] Despite this evidence, ICP monitoring in children with TBI, particularly in infants, is still not rigorously performed in clinical practice. Keenan and associates[126] surprisingly reported in 2005 that only 33% of infants and young toddlers (younger than 2 years) with severe TBI underwent ICP monitoring in the state of North Carolina. Consideration of risk versus benefit for ICP monitoring must be involved in the clinical decision in cases in which the complication rate is high, such as in patients with coagulopathy.

Since publication of the last edition of this textbook, two new studies in adult TBI are important to discuss. Supporting the use of ICP monitoring, Gerber and colleagues[127] reported on the results of a study by the Brain Trauma Foundation on all cases of TBI in the state of New York. Between 2001 and 2009, mortality decreased from 23% to 13%, which was accompanied by guidelines-based ICP monitoring increasing from 56% to 75%. In contrast, Chesnut and colleagues[128] found no differences in outcome in a study of 324 patients in Latin America randomized to treatment led by either ICP-directed care or a protocol in which treatment was based on imaging and clinical examination. A consensus-based interpretation of that study suggested that the results of the trial should not be generalized and that it should not change current practice of those currently using ICP monitoring. However, additional investigation of ICP monitoring was recommended.[129]

Currently, ICP monitoring by ventricular catheter is considered the most accurate, low-cost, reliable method.[1,2] The ventricular catheter also affords a key therapeutic option—CSF drainage. Other acceptable methods include parenchymal fiberoptic and microtransducer systems; subarachnoid, subdural, and epidural monitors of any type are less reliable.[130] The type of monitor (ventricular catheter or fiberoptic pressure transducer) used is dependent on the local preference of the neurosurgical staff.

The location of the patient in the hospital when the monitor is placed varies among centers and includes the emergency department/trauma bay, operating room, or PICU. Despite the flurry of activity that often surrounds the stabilization of a critically injured child with severe TBI, it is important to provide adequate anesthesia during placement of the monitor to prevent pain-induced spikes in ICP or herniation.

Monitoring and treatment of ICP are essential to contemporary management. Finally, use of a ventricular catheter affords the added opportunity of CSF drainage

as a therapy.

Advanced Monitoring Techniques

Monitoring Cerebral Blood Flow

Several techniques for assessing CBF, autoregulation of CBF, or metabolism can provide additional insight into the occurrence of cerebral ischemia or other metabolic derangements during management and help guide therapy. However, information on the use of these techniques and their impact on outcome in infants and children with severe TBI remains limited. Often, these methods are used only in clinical research or specialized trauma centers with particular interest in pediatric neurointensive care.

Clinically available techniques for measuring CBF after severe TBI in children include (1) transcranial Doppler (TCD) and (2) arterial spin-label MRI (ASL-MRI).[119]

TCD is gaining acceptance in pediatric neurocritical care because it is noninvasive and readily repeated at the bedside.[131,132] It can serve as an early warning monitor of the development of an unfavorable trend in cerebral perfusion; in addition, it can assess autoregulation, define major alterations, identify vasospasm, and contribute prognostic information.[8,131-133] TCD measures velocity rather than flow and usually is applied to assess the middle cerebral artery distribution. However, the inability of TCD to acquire regional data limits its utility in titrating care. Some have suggested that TCD also has utility in identifying the presence of raised ICP, but results have been conflicting.[134,135]

ASL-MRI has been used for decades in preclinical investigations in TBI and is now used routinely in advanced neurocritical care in some centers.[117,136] However, its use to assess CBF in pediatric TBI is only beginning to emerge.[137] This method is not a monitoring tool given its need for MRI; however, it provides quantitative maps of CBF and can be used for dynamic studies such as assessment of CO_2 reactivity or pressure autoregulation. Its use is likely to increase as faster MRI techniques are developed. Unfortunately, the stable xenon CT method that was used in a number of seminal studies of pediatric TBI (Fig. 119.10) is not available for routine clinical use.[18,138]

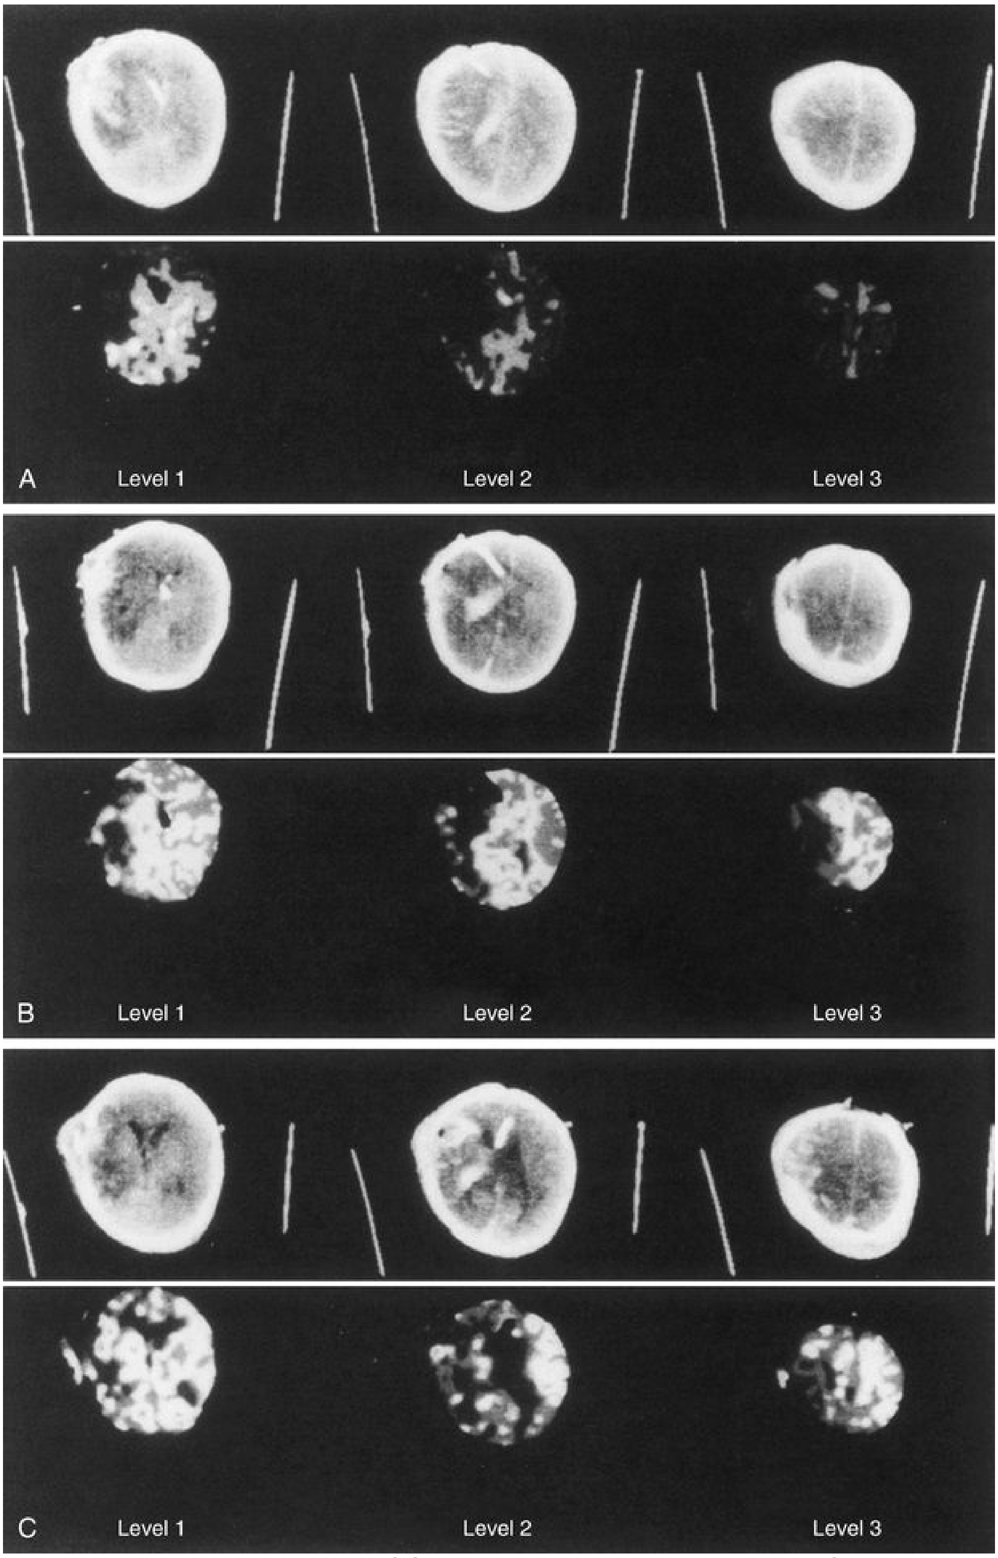

FIG. 119.10 Time course of CBF measured by Xe-enhanced CT in a 2-month-old infant after severe traumatic brain injury from a motor vehicle accident. Standard CT images *(upper row)* and Xe-enhanced CBF maps *(lower row)* are shown from studies performed on admission (A) and at 2 days (B) and 5 days (C) after injury. Flow is severely reduced *(black)* on admission. Some recovery of CBF is seen at 2 days and 5 days after injury. CBF ranges from lowest *(darkest image)* to highest *(brightest image)*.

As previously discussed, Brady and associates[62] have generated interest in continuous monitoring of blood pressure autoregulation of CBF with use of a PRx that is calculated as a linear correlation between ICP and blood pressure. With use of this noninvasive adjunct to ICP monitoring, intact autoregulation was shown to be associated with survival in 21 children with severe TBI. This method also may contribute to better definition of optimal CPP; however, it fails to provide regional assessments—further study is needed.

Monitoring Cerebral Metabolism

Jugular venous saturation has been used to monitor cerebral oxygen delivery in adults, but limited information on the utility of this technique in children is available.[53,54] Studies in adults suggest that therapies such as barbiturates and hyperventilation can be titrated according to jugular venous saturation.[139,140] Desaturations below the threshold value of 50% are associated with mortality in adults.[141] However, jugular venous desaturation below this level was rarely the sole indication that urgent intervention was needed, and false desaturations occurred. Nevertheless, this tool can assist in clinical decision making, but some persons have questioned its ability to monitor regional effects and it has not been commonly used in pediatric TBI.[142]

Several other modes of monitoring cerebral metabolic rate may be helpful. Near-infrared spectroscopy has been used to track the oxidative state of cytochromes in brain. Near-infrared spectroscopy has been used to assess cerebral metabolic status in hypoxemic-ischemic neonates[143] and is beginning to be used in pediatric TBI.[144] Although its exact role remains unclear, it may prove valuable as a trend monitor.[145] Limitations with topographic resolution and the dominance of the superficial brain tissue in generating the signal are concerns.

Monitoring partial pressure of oxygen (PO_2) in brain parenchyma ($PbtO_2$) with a microelectrode implanted in the frontal lobe is feasible.[146] A threshold value of about 8.5 mm Hg was associated with a reduction in CPP below 60 mm Hg, although in adults, thresholds anywhere from 10 to 30 mm Hg have been recommended. Use of this approach has gained interest in pediatric TBI over the past decade. Stiefel and colleagues[147] reported on the utility of $PbtO_2$ monitoring in children and suggested a threshold of 20 mm Hg. Stippler and associates reported experience with $PbtO_2$ monitoring in a series of children and found that a PbO_2 of 30 mm Hg was associated with the highest sensitivity/specificity for favorable neurologic outcome at 6 months after TBI.[148] We routinely use $PbtO_2$ in children with TBI, targeting a threshold of 20 mm Hg. Therapy is first targeted to optimize ICP and CPP. However, in some cases, $PbtO_2$ is <20 mm Hg despite control of ICP and it is necessary to evaluate other potential factors that might be affecting brain oxygenation. These factors could include inadvertant hyperventilation due to a ventilator change or a decline in PaO_2 due to lung disease; if so, these issues should be addressed. If there is no extracerebral complication affecting $PbtO_2$, interventions such as increasing FIO_2 or raising $PaCO_2$ or MAP/CPP to improve CBF may further augment $PbtO_2$. The major limitations of $PbtO_2$ are its invasiveness and provision of only focal data. In adults, $PbtO_2$ measurement has been coupled to cerebral microdialysis to provide metabolic data (ie, glutamate levels).[149,150]

Finally, positron emission tomography (PET) has been used in adults with severe TBI (Fig. 119.11).[23] Although limited by long acquisition times and the risk of intrahospital transport of critically ill patients, the metabolic maps generated provide much insight, particularly into cerebral glucose utilization after TBI. Diringer and coworkers[151] used PET to provide important insight into the effect of hyperventilation on $CMRO_2$ in adults with severe TBI (see the section on hyperventilation). Both PET and advanced MRI, along with magnetic resonance spectroscopy, can provide insight into regional brain disturbances and the effect of therapy.

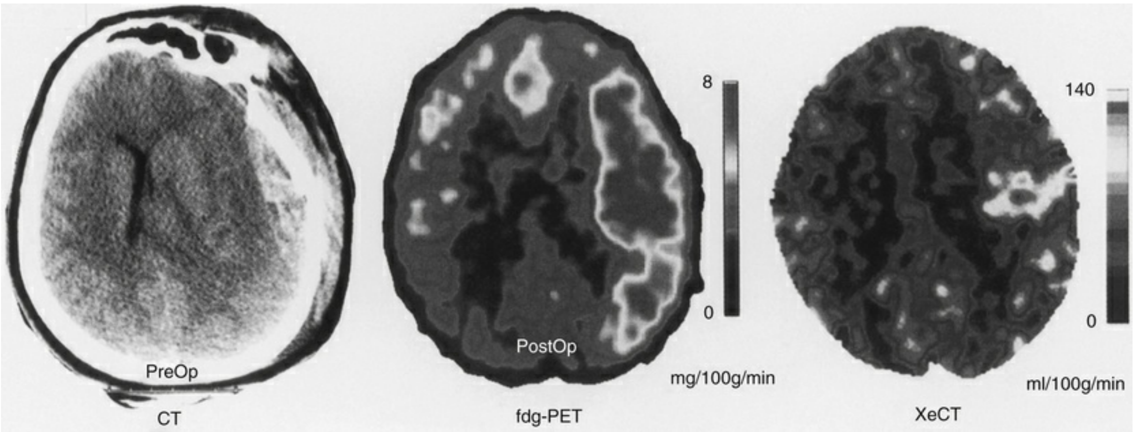

FIG. 119.11 CT image *(left)* of an acute subdural hematoma with mass effect that was treated with surgical evacuation. 18F-flurodexoyglucose positron emission tomographic (PET) map *(center)* obtained at 5 days after surgery shows marked local increases in cerebral glucose utilization in the brain regions underlying the hematoma. Stable Xe-enhanced CT CBF map *(right)* also obtained at 5 days after surgery shows increased CBF in the same region, indicating that the increase in glucose utilization is not the result of hypoperfusion. This phenomenon, termed *hyperglycolysis*, is suggested to represent increased glucose utilization by astrocytes coupled to glutamate uptake and other mediator-driven processes. This highlights the complex regional metabolic demands of the traumatically injured brain.

Treatment in the Pediatric Intensive Care Unit

Once the initial resuscitation is completed and evacuable intracranial masses have been addressed, maintenance of physiologic stability and recognition and management of raised ICP are the priorities. A flow diagram illustrating a general approach to first-tier treatments of the child with severe TBI was provided in the initial pediatric guidelines (Fig. 119.12). The injured brain has complex metabolic requirements that are poorly understood.[152] Autoregulation of CBF may be disturbed, and metabolic demands may be either decreased or increased.[15,53-56,62,153] It is clear, however, that evidence of neuronal death from cerebral ischemia is a common finding on autopsy in patients who die after severe TBI. Control of ICP and maintenance of adequate CPP and $PbtO_2$ may limit the risk of developing secondary

ischemia. The goals of management are thus to optimize ICP, CPP, and brain oxygenation/perfusion; avoid secondary insults; and create the best possible environment for brain recovery.

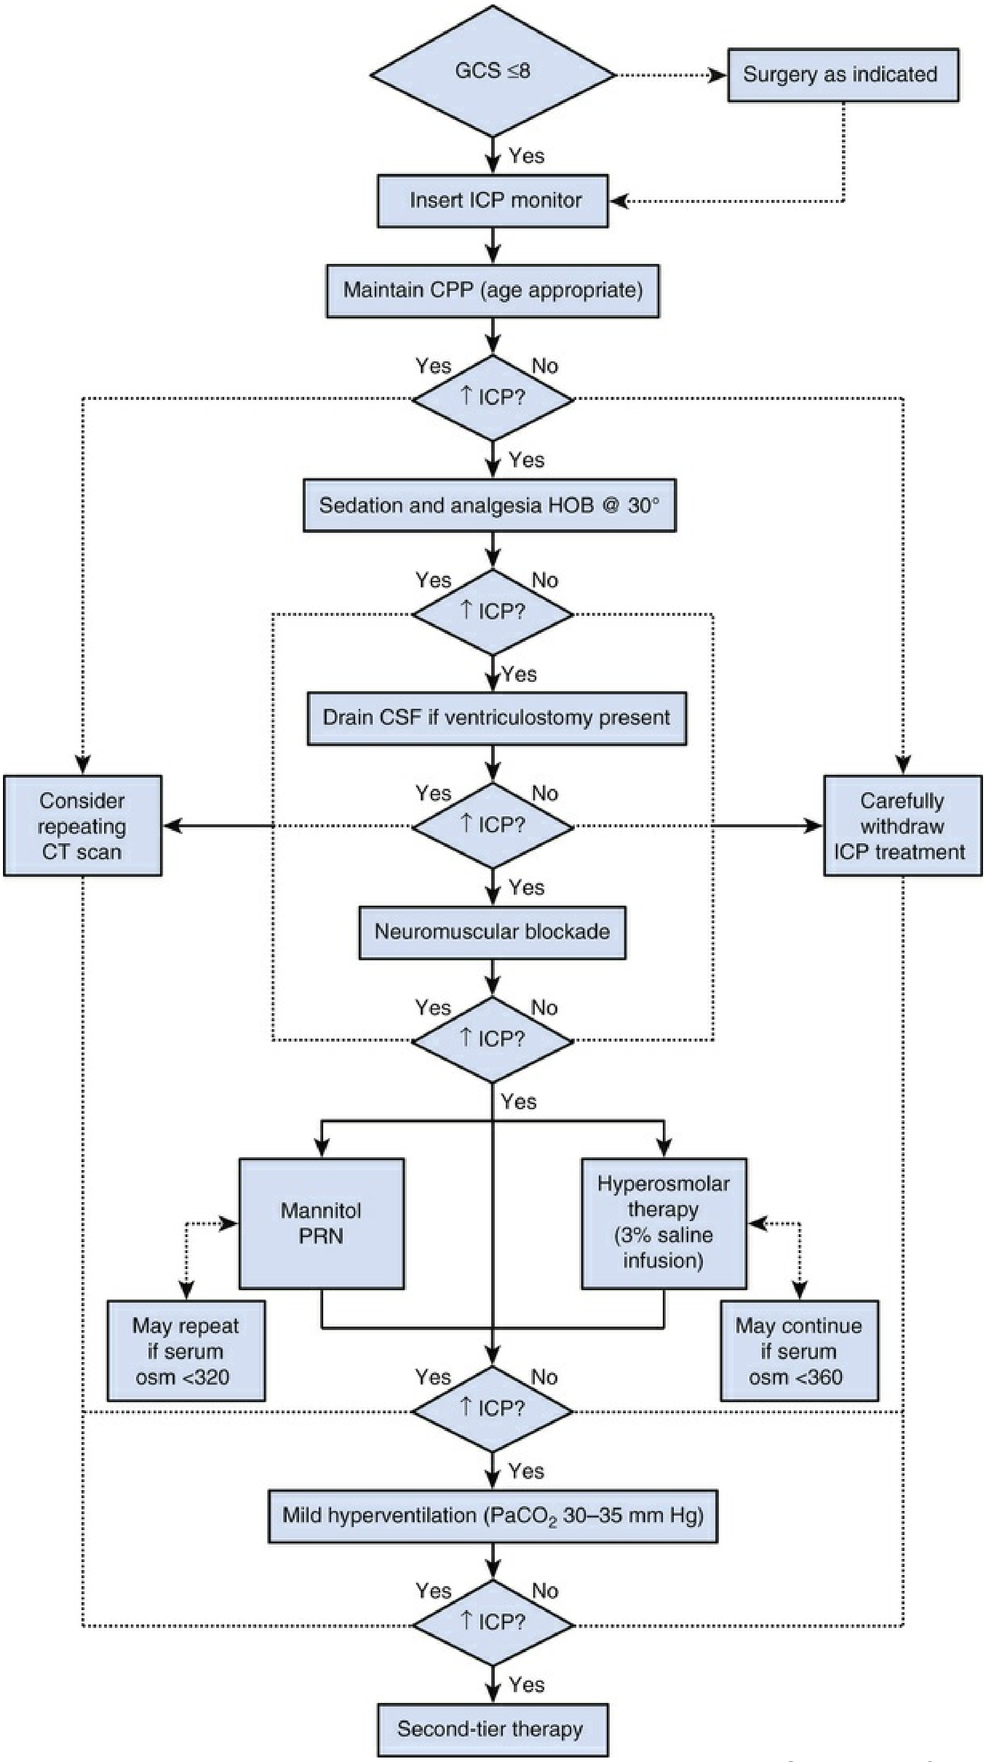

FIG. 119.12 First-tier management approach based on the Guidelines for the Management of Severe TBI in Infants, Children, and Adolescents.[1] *HOB,* head of bed.

Intracranial Pressure and Cerebral Perfusion Pressure Thresholds

Adult patients with severe TBI who have an ICP of 20 mm Hg have a poorer outcome than do those without increased ICP.[122,124,125,154] As discussed, despite the RCT showing similar outcomes for adults with severe TBI managed in Latin America with versus without ICP monitoring, a consensus-based interpretation of that study suggested that the results of the trial should not be generalized and that it should not change practice of those currently using ICP monitoring. [128,129] A prospective cohort study by Ghajar and colleagues[155] also suggested better outcome in adults monitored and treated with CSF drainage versus those without ICP monitoring. Several studies suggest that optimal outcome is achieved when even more modest levels of ICP (ie, 15 mm Hg) are the target.[155] Although no pediatric study has prospectively compared ICP treatment thresholds and their effect on outcome using a specific treatment regimen, review of the pediatric literature provides clues on the optimal ICP treatment threshold. Many studies published before the guidelines, including a total of more than 230 cases of severe pediatric TBI, reported that poor outcome was associated with ICP >20 mm Hg.[55,156-159] In an important study by Chambers and associates[160] in 99 children with head injuries (0-13 years of age) in the United Kingdom, an ICP threshold of 15 mm Hg was used. However, it remains to be determined whether a lower ICP threshold is appropriate for infants in whom physiologic MAP is lower than in adults. This issue remains as an important unanswered question.[161]

As with ICP, no RCT has been conducted to define the optimal CPP for pediatric TBI, although its importance in patient management is recognized. Reductions in CPP below specific threshold values are associated with poor outcome. The original guidelines' recommendation of 40 mm Hg was based on four studies that defined the CPP associated with poor outcome as between 40 and 65 mm Hg.[159,162-164] Several publications have further clarified the issue of optimal CPP in children, suggesting the need for age-dependent thresholds. Chambers and colleagues[165] published what is the largest study on this topic in pediatric TBI, and based on data from 235 children, they suggested minimum CPP values of 53, 63, and 66 mm Hg for children between the ages of 2 and 6 years, 7 and 10 years, and 11 and 16 years, respectively. However, that study considered only the first 6 hours of monitoring, and CPP and ICP were not addressed for patients <2 years of age. In a follow-up study of 91 children, Chambers and colleagues[160] used a pressure-time index to determine critical CPP thresholds of 48, 54, and 58 mm Hg in children aged 2 to 6 years, 7 to 10 years, and 11 to 15 years, respectively. Allen and coworkers[166] assessed data from >2000 children in the New York State Brain Trauma Foundation database and suggested CPP thresholds of >60 mm Hg in adults, 50 to 60 mm Hg in children 6 to 17 years of age, and >40 mm Hg in infants and children 0 to 5 years of age. These are reasonable recommendations until prospective trials of CPP-directed therapy in children are carried out.

In addition to the methods described later for control of ICP, titration of vasopressor or inotropic support may be necessary to achieve an appropriate level of CPP once adequate filling pressure and hemoglobin are confirmed. In some situations, as with the development of neurogenic pulmonary edema, aggressive cardiovascular monitoring and optimal titration of cardiopulmonary support can be

challenging and key determinants of outcome. Finally, not only are the optimal ICP and CPP targets likely to be important, but how one achieves these target values may be very important. DiGennaro and colleagues[167] suggested that norepinephrine was associated with the best CPP and ICP profiles compared to other pressors in pediatric TBI.

Treatment of Intracranial Hypertension: First-Tier Therapies

Ventricular Cerebrospinal Fluid Drainage

Ventricular CSF drainage has been used to manage raised ICP in adults for more than 40 years. Cerebrospinal fluid drainage for treatment of intracranial hypertension in children was shown to improve CBF in 1971.[168] Fortune and colleagues[169] compared the effect of CSF drainage and mannitol in adults after severe TBI and noted similar effects on CBF and ICP. Use of CSF drainage was associated with a greater increase in jugular venous saturation than was mannitol therapy. CSF can be drained intermittently or continuously, with threshold values for drainage determined on the basis of the clinical indication. In a small retrospective two-center comparison between continuous and intermittent CSF drainage approaches in children with severe TBI, Shore and coworkers[170] reported that continuous drainage was associated with removal of a substantially greater amount of CSF, markedly reduced CSF levels of biochemical mediators, and lower ICP. However, the efficacy of CSF drainage versus other treatments of intracranial hypertension remains unclear, and larger studies are needed. It is our clinical impression that CSF drainage reduces requirements for other therapies targeting ICP. However, this has yet to be proven. We also reported that if continuous drainage is used, inserting a second parenchymal ICP monitor may be of value because continuous drainage limits the ability to continuously monitor ICP, and spikes of intracranial hypertension could be missed.[171] Given that effectiveness of ICP control with or without CSF diversion is one of the hypotheses of the ADAPT trial, data on this important question should be forthcoming. Finally, lumbar CSF drainage can reduce ICP in cases with discernible basal cisterns; this factor is discussed in the section on second-tier therapies.

Osmolar Therapy

Based on the hypothesis that BBB permeability and increases in CBV play only limited roles in the development of cerebral swelling and that tissue osmolar load may be more important, particularly in contusion, osmolar therapies (eg, mannitol and hypertonic saline solution) seem to be logical. The BBB is nearly impermeable to both mannitol and sodium. This suggestion contrasts with traditional recommendations supporting the use of hyperventilation and avoidance of mannitol.[172,173] Despite its ubiquitous use and studies supporting its use for the management of TBI in adults, mannitol has been subjected to limited investigation in pediatric TBI. Even though mannitol is a cornerstone for management of intracranial hypertension in pediatric and adult TBI,[1,2,130] it has not been subjected to controlled clinical trials compared with placebo, other osmolar agents, or other mechanism-based therapies in children.

Mannitol reduces ICP by two distinct mechanisms.[130] First, it produces a rapid

reduction in ICP by reducing blood viscosity with a resultant decrease in blood vessel diameter and CBV.[174] This mechanism is dependent on intact viscosity autoregulation of CBF that is linked to blood pressure autoregulation of CBF. The effect of mannitol administration on blood viscosity and CBV is transient (lasting ~75 minutes).

The second mechanism by which mannitol administration reduces ICP is via an osmotic effect. This effect develops more slowly (over 15 to 30 minutes) and results from movement of water from parenchyma into the circulation. The effect persists between 1 and 6 hours and depends on an intact BBB. Changes in serum osmolality reduce brain water only in relatively normal brain regions. It has long been suggested that mannitol may accumulate in injured brain regions and a reverse osmotic shift may occur, with fluid moving from the circulation to the parenchyma, possibly exacerbating intracranial hypertension. Polderman and colleagues[66] showed in adults that after 48 hours of therapy, mannitol levels in CSF increase and in some adults with severe TBI, a reverse osmotic gradient can be seen, explaining the lack of effect of this therapy or the need for escalating doses after several days of administration. They suggested that it might be optimal to measure CSF mannitol levels to guide therapy. Others have suggested titration of mannitol to osmolar gap.[175] Mannitol is excreted unchanged in urine, and a risk for development of acute tubular necrosis and renal failure has been suggested with serum osmolarity >320 mOsm in adults. However, the literature supporting this finding dates from the late 1970s and early 1980s, an era when dehydration therapy in combination with mannitol use was common. Hyperosmolar euvolemia is targeted with contemporary mannitol use. High levels of serum osmolarity (365 mOsm) appear to be tolerated in children when induced with hypertonic saline solution, although one case series suggests the possibility of renal impairment with these high osmolarity levels in children treated with hypertonic saline solution.[176,177]

Few data support the concomitant use of diuretics and mannitol to reduce ICP. James[178] performed a retrospective study of 60 patients (ages 1 to 73 years) treated with mannitol for increased ICP. After bolus mannitol administration, ICP decreased after 116 of 119 doses. The reduction in ICP in response to mannitol administration was dose dependent between 0.18 and 2.5 g/kg. In contrast, Marshall and colleagues[179] reported equivalence for doses between 0.25 and 1 g/kg in adults. Despite a remarkable track record for controlling ICP in TBI, clinical investigation of mannitol use in infants and children is lacking. Surprisingly, an epidemiologic study suggested that mannitol use was associated with prolonged PICU length of stay but no survival advantage.[180] Nevertheless, it remains a first-tier therapy in severe pediatric TBI.

Use of hypertonic saline for treatment of raised ICP was first described in 1919 but failed to gain clinical acceptance.[181] Interest in this treatment has undergone a resurgence. Penetration of sodium across the BBB is low. Sodium has a reflection coefficient higher than that of mannitol and shares with mannitol both the favorable rheologic effects on CBV and osmolar gradient effects. Hypertonic saline exhibits other theoretic benefits, such as restoration of cell resting membrane potential, stimulation of atrial natriuretic peptide release, inhibition of inflammation, and enhancement of cardiac performance.

Hypertonic saline was studied in more than 130 pediatric patients with severe TBI. There are two types of studies: (1) treatment of refractory intracranial hypertension

and (2) comparison of hypertonic saline solution to maintenance fluid as a continuous infusion. Fisher and coworkers[105] compared 3% saline solution and 0.9% saline solution in children with severe TBI. During the 2-hour trial, hypertonic saline solution was associated with a lower ICP. The serum sodium level increased about 7 mEq/L after administration of 3% saline solution. Khanna and associates[182] reported a prospective study of 3% saline solution (514 mEq/L) given on a sliding scale to maintain ICP <20 mm Hg in children with resistant intracranial hypertension. A reduction in ICP and an increase in CPP were noted with 3% saline solution. The mean highest serum sodium level and osmolarity were about 170 mEq/L and approximately 365 mOsm/L, respectively. Sustained hypernatremia and hyperosmolarity were generally tolerated. Acute renal failure developed in two patients.

Peterson and colleagues[176] reported a retrospective study on the use of a 3% saline solution infusion titrated to reduce ICP to ≤20 mm Hg in infants and children with TBI. The mean daily doses of hypertonic saline solution ranged from between 11 and 27 mL/kg/day. A control group was not used, but only three patients died of uncontrolled ICP, and 73% of patients had a good or moderate outcome. Rebound in ICP or other adverse effects were not seen.

Theoretic concerns associated with use of hypertonic saline solution include development of extrapontine myelinolysis (EPM), rapid shrinking of the brain associated with mechanical tearing of bridging vessels leading to subarachnoid hemorrhage, renal failure, and rebound intracranial hypertension.[183] EPM is related to central pontine myelinolysis (CPM) but occurs with hypernatremia or its correction. It is characterized by demyelination of the thalamus, basal ganglia, and cerebellum.[184] Neither EPM nor CPM has been reported in human trials of hypertonic saline solution for treatment of TBI. EPM has been reported in dehydrated children with serum sodium levels of 168 to 195 mEq/L, and CPM has been reported with rapid correction of chronic hyponatremia.[185] Peterson and colleagues[176] performed MRI evaluations in 11 patients in their study, and none had evidence of CPM. However, rats with normal serum sodium levels subjected to increases of 39 mEq/L showed severe demyelinating lesions.[186] Similarly, subarachnoid hemorrhage has been reported with serum sodium concentrations from 149 to 206 mEq/L within 1 hour after injection of 9% hypertonic saline solution in normal kittens.[187]

Renal failure is a concern with use of hyperosmolar therapies,[188] but this complication seems uncommon with hypertonic saline solution use in children after TBI.[176,177] Rebound intracranial hypertension has been described with use of hypertonic saline solution bolus therapy or after cessation of continuous infusion.[176,189] As with mannitol therapy, if the BBB is breached, one would also expect that CSF levels of sodium would gradually increase with prolonged therapy. Patients may require progressive increases in infusion rates to control ICP. Subsequent to publication of the most recent update to the guidelines,[2] Gonda and associates[190] reported that serum sodium levels >170 mEq/L were associated with a higher occurrence of thrombocytopenia, renal failure, neutropenia, and acute respiratory distress syndrome after controlling for key confounding variables in 88 children with raised ICP. Thus caution is indicated in refractory cases; multiple therapies to control ICP rather than advancing hypertonic saline to higher risk levels should be strongly considered. Given all of the evidence, hypertonic saline solution,

mannitol, and CSF drainage are first-tier therapies for raised ICP after severe TBI in infants and children.

Sedation Analgesia and Neuromuscular Blockade

Sedation and neuromuscular blockade should be used as needed in the setting of raised ICP once appropriate monitoring has been established and thus are integrated into first-tier treatment. Narcotics, benzodiazepines, or small doses of barbiturates are generally recommended for routine use. To our knowledge, no controlled trial of varying sedation regimens has been performed in pediatric patients with severe TBI. Hsiang and colleagues[191] reported on 514 adults with severe TBI and suggested that prophylactic neuromuscular blockade was associated with increased length of ICU stay and nosocomial pneumonia. However, the study was not prospective and should not preclude the use of neuromuscular blockade in pediatric TBI. A systematic review on the use of neuromuscular blockade in adults identified a number of small studies showing benefit on various aspects of ICP care including preventing increases in ICP during tracheal suctioning or on spontaneous ICP spikes.[192] Careful assessment of indication and titration is essential. Finally, intermittent doses of barbiturates or lidocaine may be needed to blunt excessive rises in ICP resulting from routine patient care maneuvers such as suctioning. Additional studies are badly needed.

Head Position

Feldman and colleagues[193] conducted a prospective RCT of the effect of head position on ICP, CPP, and CBF in 22 adults after severe TBI. Both ICP and mean carotid pressure were reduced in the 30-degree position versus the 0-degree position. CPP and CBF did not change with this intervention. Thus, in general, the 30-degree head-elevated position reduced ICP without deleterious effects on CPP and is preferred. Head elevation and midline position improve jugular venous and possibly CSF drainage and decrease the contributions of these components to ICP.

Treatment of Intracranial Hypertension: Second-Tier Therapies

Refractory intracranial hypertension occurs in 20% to 40% of cases of severe pediatric TBI and is associated with mortality rates of 30% to 100%.[156-159,162-164,180,194,195] Several second-tier therapies are available for treatment of refractory intracranial hypertension (Fig. 119.13). Second-tier therapies include barbiturates, hyperventilation, hypothermia, decompressive craniectomy, and lumbar CSF drainage.

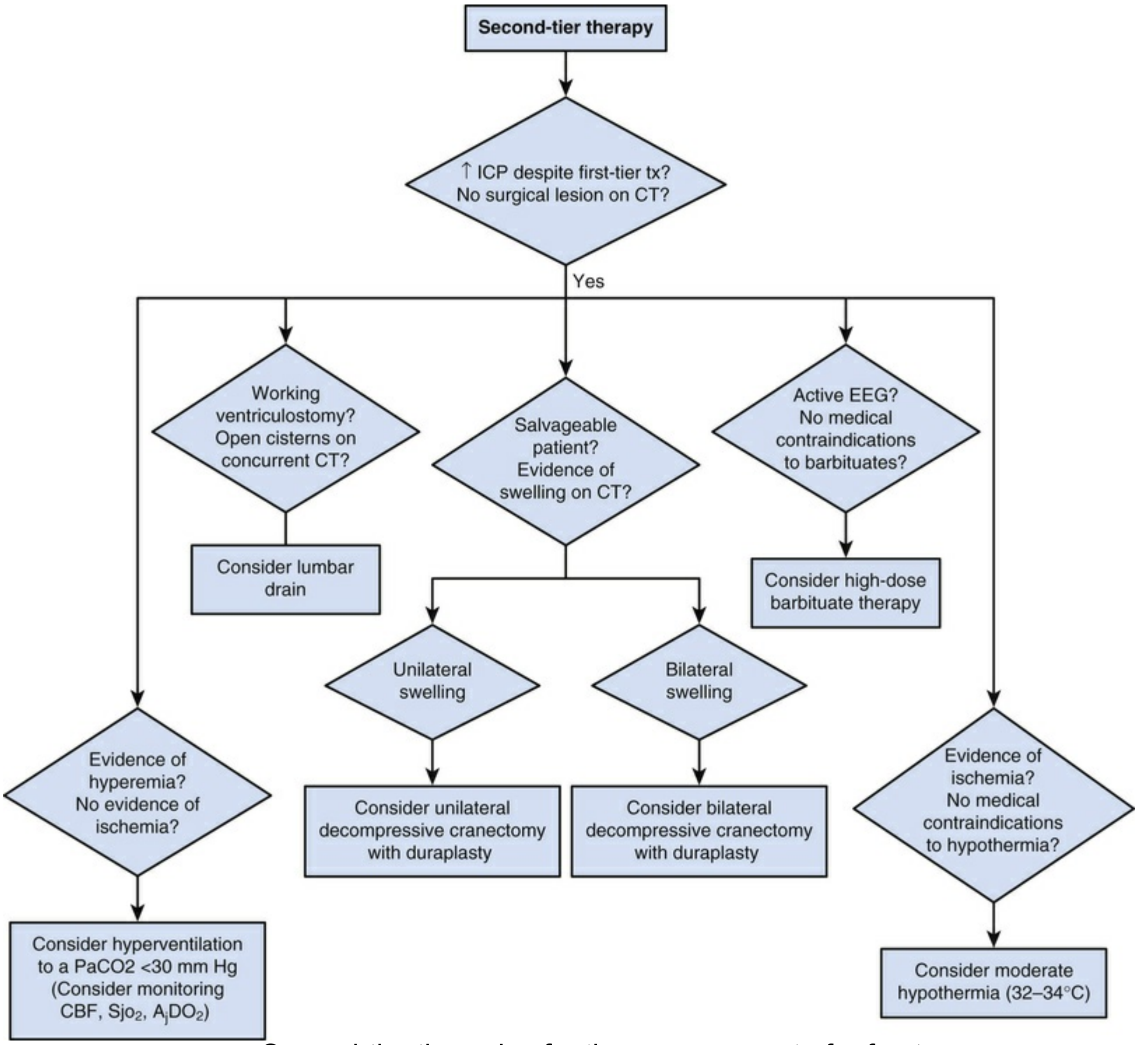

FIG. 119.13 Second-tier therapies for the management of refractory intracranial hypertension based on the Guidelines for the Management of Severe TBI in Infants, Children, and Adolescents.[1] A_jDO_2, arteriojugular venous oxygen content difference; Sjo_2, jugular vein oxygen saturation.

Barbiturates

Barbiturates produce a reduction in ICP via a decrease in cerebral metabolic rate. Although an RCT of barbiturate therapy for treatment of severe TBI in adults did not show an outcome benefit,[196] it can be effective in the setting of refractory raised ICP.[197] Goodman and coworkers[198] reported an improvement in brain interstitial concentration of lactate and glutamate accompanying a reduction of ICP in seven adults treated with barbiturates for refractory intracranial hypertension. Subsequent to publication of the revised guidelines, Mellion and colleagues[199] published additional supportive data for the use of high-dose barbiturates after severe TBI in 36 children with refractory raised ICP. Ten of the 36 patients responded with control of ICP (<20 mm Hg). Control of refractory ICP was associated with better long-term outcome. If either frequent dosing or barbiturate infusion is used, an electroencephalogram (EEG) should be used to assess the response to treatment. The endpoint of barbiturate coma is generally burst suppression. Pentobarbital often is infused to achieve a burst suppression response on EEG. However, that goal should

only represent the maximal barbiturate dose used for ICP control because (1) smaller doses—those still associated with EEG activity—may be adequate to control ICP, and (2) indiscriminate use can be associated with undesirable adverse effects such as hypotension.[200] When barbiturates are used, hypotension should be avoided. Patients should be carefully monitored for reduced cardiac output or inadequate systemic perfusion, as clinically indicated.

Hyperventilation

Hyperventilation has been used to manage pediatric patients with severe TBI since the 1950s.[201] Bruce and colleagues[17] suggested that hyperemia was the predominant mechanism involved in the development of raised ICP in children. Until the mid-1980s, prophylactic hyperventilation was the standard of care. In addition to reducing postinjury hyperemia, hyperventilation was suggested to reduce brain acidosis and restore CBF autoregulation. Subsequently, studies in experimental models suggested hyperventilation had deleterious effects. Prophylactic hyperventilation depletes brain interstitial bicarbonate buffering capacity and is accompanied by a gradual loss of local vasoconstrictor effects.[202]

In an RCT in adults after severe TBI, prophylactic hyperventilation for 5 days to a $Paco_2$ of about 25 mm Hg versus about 35 mm Hg was associated with worse outcome.[203] Skippen and colleagues[4,119] reported that hyperventilation to a $Paco_2$ of about 25 mm Hg reduced CBF to levels less than 18 mL/100 g/min in 73% of infants and children with severe TBI (Fig. 119.14). Coles and associates[142] found similar results in adults. However, neither of these studies assessed the effect of hyperventilation on either regional cerebral metabolism or neurologic outcome. In experimental TBI in rats, aggressive hyperventilation ($PaCO_2$ ~20 mm Hg) early after injury increased hippocampal cell death. The most recent pediatric guidelines recommend that prophylactic hyperventilation (Pa_{CO2} <30 mm Hg) should be avoided and that if it is used to control refractory intracranial hypertension, advanced neuromonitoring may be considered.[22]

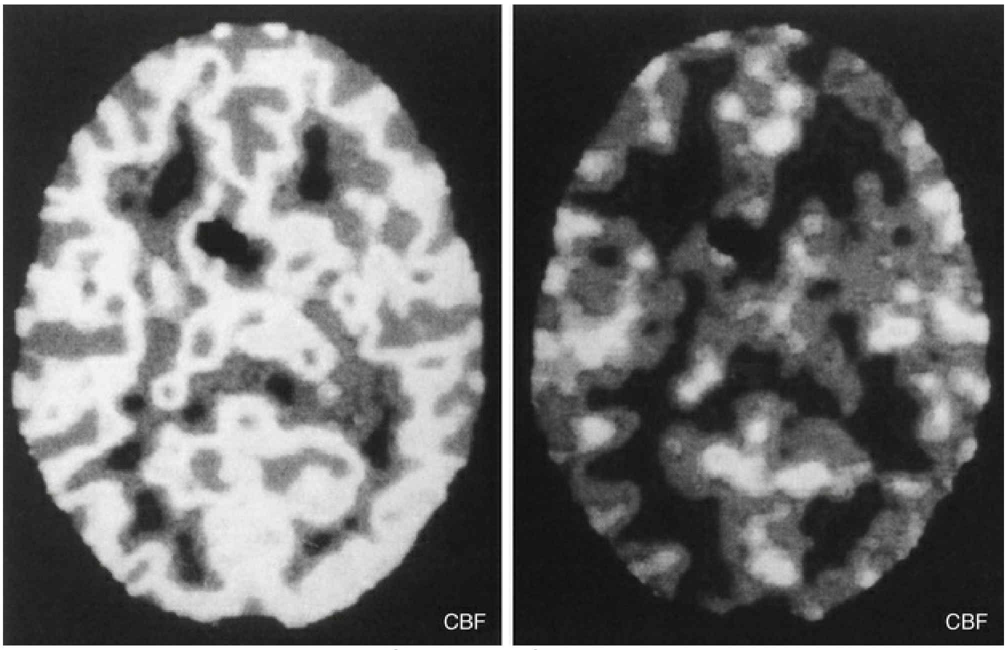

FIG. 119.14 Xe-enhanced CBF maps from a child with severe traumatic brain injury before *(left)* and after *(right)* escalation of hyperventilation (a second-tier therapy) in the scanner. Intact reactivity of CBF to change in $PaCO_2$ is demonstrated by an obvious reduction in flow. CBF ranges from lowest *(darkest image)* to highest *(brightest image)*.

Supporting this approach in infants and children, early after severe TBI, hypoperfusion rather than hyperemia was shown to be associated with poor outcome.[18] However, the risks of hyperventilation are still somewhat controversial. Diringer and colleagues[151] reported that at between 8 and 14 hours after severe TBI in adults, hyperventilation ($PaCO_2$ ~30 mm Hg) reduced CBF but did not further reduce cerebral metabolic rate for oxygen as assessed using PET. This finding suggests that in TBI, after the acute hypermetabolic phase, hypometabolism follows and hyperventilation may be a relatively safe means to reduce ICP in the PICU. This study did not evaluate outcome. In contrast, several reports in adults suggest deleterious effects of hyperventilation after TBI, including increases in brain interstitial levels of glutamate and lactate[205] and higher ischemic brain volumes.[206]

Based on these data, there is waning support for the use of hyperventilation. At Pittsburgh Children's Hospital, with the addition of $PbtO_2$ monitoring, when ICP is controlled but $PbtO_2$ is <20 mm Hg, we have found that careful limitation of even mild hyperventilation can, in some cases, promptly increase $PbtO_2$. Despite these concerns, hyperventilation surprisingly seems to remain a mainstay of care in pediatric TBI. Curry and associates,[207] in a study of 375 children with severe TBI, reported a 52% to 60% incidence of substantial hypocarbia ($PaCO_2$ <30 mm Hg) in the initial 48 hours that was associated with poor outcome. This incidence was seen despite ICP levels less than 20 mm Hg in many cases. A high frequency of hyperventilation also was reported by Morris and colleagues[208] in the United Kingdom database and, surprisingly, in the RCT of therapeutic hypothermia by the Canadian multicenter trials group (44%).[209] Some investigators have suggested that it may be time to set the alarm threshold for $PaCO_2$ in management of severe TBI in children or for a practice bundle in TBI.[210] Nevertheless, its use as adjunct treatment

of refractory raised ICP, particularly during the delayed postinjury phase, was supported as a second-tier therapy in the guidelines. Based on the current state of knowledge, if hyperventilation ($PaCO_2$ ~30 mm Hg) is used to manage refractory ICP, advanced neuromonitoring such as assessment of $PbtO_2$, CBF, or jugular venous oxygen saturation is recommended to prevent iatrogenic ischemia. Finally, the optimal approach to ventilation is one of the aims within the ADAPT comparative effectiveness trial, so additional information should be forthcoming from that important multicenter investigation.

Hypothermia

In experimental models of TBI and in some clinical trials in adults after TBI, hypothermia improved outcome, presumably via multiple mechanisms, and meta-analyses supported its use in adults with severe TBI.[211-213] However, unlike the case in hypoxic ischemic encephalopathy (HIE) in newborns, RCTs of hypothermia targeting a temperature of about 33°C for 24 or 48 hours in children[209,214] failed to show benefit. Hutchison and colleagues,[209] in a study of 225 children randomly assigned to hypothermia versus normothermia for 24 hours, observed a trend toward worse outcome and increased mortality with hypothermia treatment. A subsequent trial by Adelson and colleagues of 48 hours of moderate hypothermia with slow rewarming was stopped because of futility.[214] These trials indicate that prophylactic hypothermia should not be routinely used as a first-tier therapy for severe TBI in infants and children.

In contrast, hypothermia remains useful as a second-tier therapy for the management of refractory intracranial hypertension after severe TBI.[215,216] Unlike studies showing benefit from transient use (12-24 hours) of mild hypothermia (33°C) in adults after cardiac arrest,[217,218] a variety of temperature ranges are necessary to control ICP; thus a titrated approach to use of hypothermia in this setting is suggested.[215,216] Rewarming should be carried out carefully, at a rate no faster that 1°C every 4 hours—or even more slowly—and great care should be taken to monitor and treat hypotension that can occur with peripheral vasodilation during rewarming. Finally, hyperthermia is extremely deleterious in experimental models of TBI, exacerbating neuronal death. This effect is seen even when a brief 3-hour period of clinically relevant hyperthermia (39°C) is applied. Natale and colleagues[219] supported the clinical relevance of this work by showing that early hyperthermia (38.5°C within the first 24 hours of admission) occurred in 29.9% of pediatric TBI patients and was associated with poor outcome and increased length of stay. The most definitive clinical study on this matter is in the area of perinatal HIE, where just 1°C of hyperthermia after HIE was associated with a deleterious effect on long-term outcome.[220] Care should be taken to treat or prevent hyperthermia after severe TBI.

Decompressive Craniectomy

Another controversial area in the management of both adults and children with refractory intracranial hypertension is the use of decompressive craniectomy. Cushing[221] initially described this modality in 1905. Decompressive craniectomy is a controversial therapy that is based on the complex metabolic demands of the brain and the equally complex but poorly understood adverse effects of many of the therapies used to treat refractory intracranial hypertension (ischemia,

hyperosmolality, metabolic suppression, and hypotension). However, this simplistic approach may have merit.

Several contemporary pediatric studies have been performed. Cho and colleagues[222] reported on the use of decompressive craniectomy versus medical management for treatment of infant victims of AHT with refractory intracranial hypertension. Although the series was small, they reported an improved outcome compared with medical therapy, with some survivors showing good outcome. This study is one of the few specifically examining treatment of patients with AHT. Polin and associates[223] reported on the use of extensive bifrontal decompressive craniectomy for the management of 35 adults and children with severe TBI and either refractory intracranial hypertension or diffuse edema on CT scan. They reported a favorable percentage of survivors with good or moderate disability (improved outcome versus retrospectively matched cases from the Traumatic Coma Data Bank) and suggested a 48-hour time window for successful use. However, the patients in this report generally were not treated with either CSF drainage or barbiturates. Nevertheless, the best results were seen in the children in this study. Taylor and colleagues [224] reported on an RCT of early decompressive craniectomy versus standardized medical management alone. Although the sample size was limited (n = 27 children), strong trends toward reduction in ICP and improvement in long-term outcome were seen with decompressive craniectomy. Jagannathan and coworkers[225] reported 81% favorable outcome in 23 children with severe TBI treated with decompressive craniectomy. Subsequent to the preparation of the revised guidelines, Cooper and associates[226] reported on an RCT of decompressive craniectomy in 155 adults with diffuse TBI and intracranial hypertension refractory to first-tier therapy. Although craniectomy reduced intracranial hypertension versus standard care, surprisingly, it was associated with more unfavorable outcomes. Patients with mass lesions were excluded in this trial, and thus it informs us only on patients with diffuse injury; nevertheless it certainly argues against prophylactic decompressive craniectomy in that population.

Decompressive craniectomy is a second-tier therapy that is used with varying frequency depending on local experience and the discretion of the management team. A large RCT (the RESCUEicp study) was completed in 400 patients in the United Kingdom, but the results have not been released.[227]

Lumbar Cerebrospinal Fluid Drainage

Lumbar CSF drainage can be effective in treating refractory intracranial hypertension in children. Levy and colleagues[228] reported that controlled lumbar CSF draining reduced refractory ICP in 14 of 16 pediatric patients and eliminated the need for barbiturates in their series. In adults with severe TBI, Munch and colleagues[229] reported an immediate and lasting reduction in ICP in 23 patients with refractory intracranial hypertension. This modality is also a second-tier treatment option, but to avoid the risks of herniation, the patient must have open basal cisterns and no important mass effect or shift, and a functional ventriculostomy must already be in place.

Controlled Arterial Hypertension

Induced arterial hypertension is a controversial approach to the management of

refractory raised ICP. Whether pressure autoregulation of CBF is intact or defective, arterial hypotension or inadequate CPP must be avoided. If pressure autoregulation is impaired, CBF is directly related to CPP and hypotension reduces flow. If pressure autoregulation is intact, then as CPP is reduced, reflex cerebral vasodilatation occurs (to maintain flow), which increases CBV and ICP.[230] This latter phenomenon occurs as CPP is reduced within the autoregulatory range. Based on the relationship among CPP, vessel diameter, CBV, and ICP in selected adults with refractory intracranial hypertension, induced arterial hypertension (CPP increased in adults to between 100 and 140 mm Hg via infusion of phenylephrine) produced a reduction in ICP.[230] However, arterial hypertension reduces ICP only when pressure autoregulation of CBF is intact because hypertension-mediated reduction in vessel caliber produces the reduction in CBV (to maintain a constant flow) and resultant reduction in ICP.

Use of this intervention is complex in pediatric TBI because a single general threshold value of CPP is not applicable. Management must be tailored to each individual patient. It is possible that the aforementioned pressure reactivity index approach could help guide this intervention.[62] Also, the short-term and long-term effects of the greater hydrostatic pressure on the development of cerebral edema are unclear. Optimal management of blood pressure after severe TBI requires both monitoring of the involved factors and an in-depth understanding of the mechanisms.[230] Induced hypertension is a controversial last-ditch therapy that is not addressed in either version of the pediatric guidelines.[1,2] Finally, a few groups managing adults with severe TBI have adopted a very different therapeutic approach to blood pressure and ICP management termed *the Lund concept.* This approach includes aggressive control of ICP with the unusual combination of β-blockade, α_2-receptor agonists, ergotamine, and barbiturates, with avoidance of systemic hypertension.[231] In some sense, this represents a form of chemical hyperventilation—that is, a pharmacologically controlled reduction in CBV. Remarkably, this approach has produced good outcome data and no exacerbation of ischemia, as assessed using intracerebral microdialysis in adults.[232] One report of this approach to ICP control in children with meningitis is available,[233] along with one report in children with TBI.[234] For additional insight into this approach, the reader is referred to the work of Stahl and associates.[232] This approach requires additional study in children.

Miscellaneous

Seizures should be treated aggressively because excessive metabolic demands in the setting of hypoperfusion could result in a second insult to an already compromised brain. Vespa and colleagues[235] in 20 adults with severe TBI showed that posttraumatic subclinical status epilepticus was associated with a considerable burden in raised ICP and long-lasting increases in the brain interstitial lactate/pyruvate ratio—a marker of ischemia. This finding has heightened interest in this area and suggests the consideration of continuous EEG monitoring in pediatric TBI. We utilize continuous EEG in all severe TBI patients in our center in Pittsburgh. However, regarding treatment the pediatric guidelines support the use of prophylactic phenytoin only as a treatment option to prevent early posttraumatic seizures in severe TBI because it has not been shown to improve outcome either

acutely or in the prevention of the late development of epilepsy.[1,2] Additional anticonvulsants are recommended to be given as needed to treat seizures. Levetiracetam has also been suggested to confer favorable effects versus phenytoin in preclinical TBI models.[35] However, a prospective study of levetiracetam versus phenytoin use in seizure prophylaxis in >800 adults with severe TBI showed no difference in occurrence of seizures—although long-term functional outcome was not reported.[236]

Even if hypertonic saline solution is not used as a therapy, careful attention should be paid to the serum sodium level. It should be monitored at least twice daily in children with severe TBI. To prevent the development of hyponatremia, we recommend using 0.9% normal saline solution as the initial intravenous fluid for children with severe TBI. For infants, D_5 (5% dextrose) normal saline solution can be used. Hyponatremia that develops while only isotonic fluids are being administered generally can be attributed to either syndrome of inappropriate antidiuretic hormone secretion or cerebral salt wasting.[237] Care should be taken to determine the correct cause of hyponatremia because the management of syndrome of inappropriate antidiuretic hormone secretion involves fluid restriction, whereas that of cerebral salt wasting involves the administration of isotonic or hypertonic saline solution.

It has long been known that hyperglycemia exacerbates experimental ischemic brain injury, and threshold values greater than 200 mg/dL are generally considered as the target. Similarly, countless studies have shown associations between hyperglycemia and poor clinical outcome after various CNS insults, and most textbooks of adult neurocritical care recommend withholding glucose in intravenous fluids for at least 24 hours unless hypoglycemia is seen. Supporting this concept, Van den Berghe and colleagues[238] reported that insulin administration to control blood glucose at less than 110 mg/dL in 63 adults with isolated brain injury from various causes produced benefits with regard to ICP, CPP, and seizures. Subsequent to the guidelines, Smith and associates[239] reported that in a cohort of children with severe TBI, exogenous glucose could be safely withheld for 48 hours after injury (mimicking the approach generally taken in cases of severe TBI in adults) with careful monitoring and the addition of dextrose if blood glucose was <70 mg/dL. With that approach, hyperglycemia in the initial 48 hours was not associated with unfavorable outcome. In contrast, Vespa and associates,[240] using intracerebral microdialysis in adults with severe TBI, reported that tight glucose control (serum glucose 90 to 119 mg/dL) produced a metabolic crisis in the brain (increases in glutamate and lactate/pyruvate ration) versus less rigorous glucose control (serum glucose 119 to 150 mg/dL). Controversy remains as to the optimal management strategy for glucose administration and control after severe TBI. Glucose management is another hypotheses being addressed in the ADAPT trial, and thus additional information on this facet of management should be available in the future.

The provision of adequate nutrition is essential during the catabolic response to critical illness, and beneficial effects of early feeding (either enteral or parenteral) in the critically ill or injured patient are well described. In critically ill adults, a cumulative deficit of 10,000 kcal was associated with increased mortality, and in the PICU this amount can be easily surpassed in less than 1 week.[241] A study using indirect calorimetry in 13 children with severe TBI by Mtaweh and colleagues,[242] however, suggests that with contemporary management, equation-based estimates

of energy expenditure greatly overestimate caloric needs, which were only 70% of predicted. This argues against a hypermetabolic response and suggests new nutritional targets or the use of calorimetry-guided nutritional support. Hyperalimentation formulations containing glutamate have been shown to increase glutamate levels, possibly exacerbating excitotoxicity.[243] Curiously, studies in experimental brain injury suggest that starvation for 48 hours dramatically reduces ultimate damage.[244] Ketosis is suggested to confer this benefit. The optimal nutritional approach in severe TBI needs to be addressed.

Routine use of glucocorticoids for treatment of patients with severe TBI is not recommended.[1,2] However, hypotension in the setting of severe TBI in rare cases is associated with pituitary failure, possibly from vascular disruption.[245]

Linking Rehabilitation and Acute Care

Rehabilitation can have dramatic effects after a severe TBI is sustained, particularly in the setting of focal injury. Successful rehabilitation may require prolonged therapy (months or even years).[246] Underscoring the potential importance of the subacute and rehabilitation phases for targeted therapy in severe TBI, Giacino and associates[247] reported, to our knowledge, the only successful clinical multicenter RCT in severe TBI in 184 adults. In that work, a 4-week exposure to amantadine—an NMDAR antagonist and dopamine agonist—resulted in significantly faster recovery of the Disability Rating Scale. Given that since the last edition of this textbook RCTs of hypothermia, decompressive craniectomy, erythropoietin, and progesterone,[214,226,248,249] among other agents, have failed in the acute phase after TBI, therapeutic trials in the subacute or rehabilitation phases after severe TBI have considerable potential and merit additional investigation. Finally, novel approaches such as the use of stem cells are also in the exploratory phase of clinical investigation and warrant investigation in children after severe TBI.[250]

Outcomes

Outcome from severe TBI generally has been assessed as a function of age at the time of injury and in relationship to three diagnostic categories: noninflicted (accidental) closed head injuries, AHT (child abuse), and penetrating injury (predominantly gunshot wounds). Accurate assessment of long-term outcome has been somewhat hampered in infants and children by the lack of validated outcome assessment tools. Application of modifications of adult outcome tools (eg, the Glasgow Outcome Scale) has been the general approach; however, these tools have limitations when applied across the pediatric age spectrum.[251] In an important paper on pediatric outcomes, Levin and colleagues[9] highlighted the dramatic effect of age on outcome. About two-thirds of children between the ages of 5 and 10 years had favorable outcome (ie, normal or moderate disability), whereas over 60% of children age 4 years or younger died. Rates of favorable outcome as high as 73% have been reported in clinical trials in pediatric TBI.[176] Specific studies of AHT and gunshot wounds generally have reported poorer outcome than series of accidental TBI. However, even in these two high-risk diagnostic categories, favorable outcome in some series has been as high as 35% in patients with severe TBI resulting from AHT

and 24% in patients with severe TBI resulting from gunshot wounds.[222,252] Public interest in the field of TBI has soared related to the emerging recognition of a potential link between repetitive mild TBI and neurodegenerative diseases such as Alzheimer disease, Parkinson disease, and chronic traumatic encephalopathy, among others (Fig. 119.15).[253] This could also occur in severe TBI and is likely in AHT, and it is under investigation.

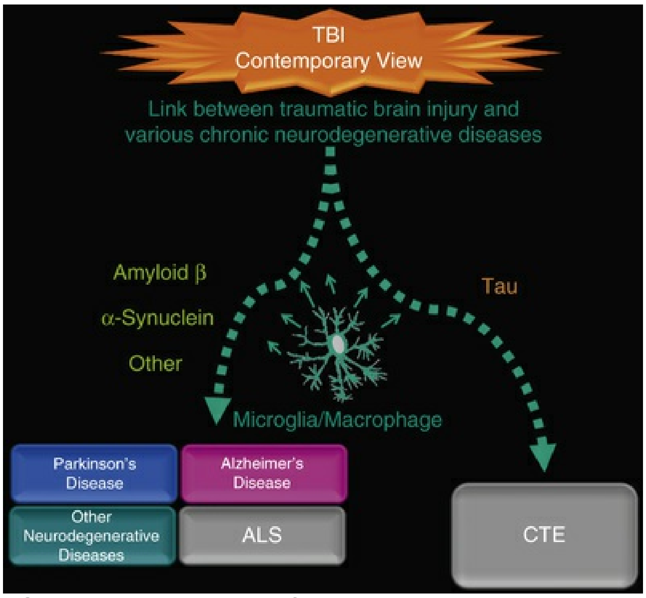

FIG. 119.15 Contemporary view of the link between traumatic brain injury (TBI) and the ultimate development of neurodegenerative diseases. This includes the progressive accumulation of amyloid β or α-synuclein in traditional neurodegenerative diseases or tau protein in chronic traumatic encephalopathy (CTE). Please see text for details. *ALS*, amyotrophic lateral sclerosis.

Conclusion

Optimal care of the infant or child with severe TBI requires a multidisciplinary approach. Prompt and vigorous resuscitation, including stabilization and control of ventilation, is essential. After initial evaluation and surgical intervention, where appropriate, monitoring and carefully titrated management of raised ICP are essential to optimize cerebral perfusion and facilitate metabolic homeostasis. Meticulous and optimal neurointensive care is the basis on which future targeted therapies will be delivered as additional information on the evolution of secondary neuronal damage becomes available. The goal of contemporary pediatric neurointensive care is the prevention of secondary injury. Much of that care focuses on preventing secondary insults. The goal of future pediatric neurointensive case will be to overlay, on this therapeutic plan, strategies manipulating tissue injury in the evolution of secondary damage at a cellular level, along with strategies to foster regeneration and rehabilitation.[29]

CHAPTER 120

Thoracic Injuries in Children

Tamara N. Fitzgerald

PEARLS

- Rib fractures are uncommon in children and indicate significant traumatic energy delivery.
- Children can maintain a normal blood pressure with up to a 40% blood loss, thus a profound state of hypovolemia may not be immediately apparent.
- Pediatric patients are vulnerable to hypothermia, due to their high body surface–to–volume ratio
- Chest radiograph is a sufficient screening tool for thoracic injury unless there is significant symptomatology to justify computed tomography.
- Echocardiography and measurement of cardiac enzymes are useful for diagnosing cardiac injury
- Identification of a diaphragmatic injury on imaging is challenging and requires a high index of suspicion.

Epidemiology and Prevention

Trauma is a leading cause of morbidity and mortality in children worldwide,[1] and it is the leading cause of death for children in the United States. Thoracic injuries account for 4% to 13% of pediatric trauma admissions.[2] Mortality from thoracic trauma is 15% to 25% and is second only to brain injury mortality.[3] The National Pediatric Trauma Registry was established in 1994 and remains an important source of information for trauma research and public health reform.

Thoracic trauma can be divided into blunt and penetrating injury. Blunt injuries account for the majority of pediatric chest trauma (92%) and include such mechanisms as falls, motor vehicle collisions, pedestrian accidents, sports injury, and child abuse. Penetrating injuries such as gunshot wounds and stab wounds are less common in the pediatric population but are increasing in urban areas. The majority of penetrating injuries occur in adolescents. School shootings have sparked public concern for this issue.

Adolescent girls have a lower mortality following traumatic shock than adolescent boys, but this gender discrepancy was not seen in prepubescent children.[4] In general, mortality is lowest for isolated thoracic injuries (5%) but increases with multisystem injury (up to 39%).[5] Infants and toddlers are often victims of child abuse and motor vehicle crashes. School-aged children 5 to 9 years old are most often injured as pedestrians struck by motor vehicles, whereas older children (10-17 years old) are most often injured on bicycles and skateboards. Older teenagers can be injured during high-risk behavior, high-impact sporting activities, motor vehicle accidents, violence, and suicide.[6] Obesity does not impact the severity of injury, mortality rate, or procedural outcomes in children. However, obese children are more likely to have rib and pelvic injuries.[7]

Anatomic and Physiologic Considerations

Children are not just small adults; they vary considerably in anatomy and physiology. This is particularly true of the thoracic organs, where the chest wall of a child is much more compliant because children have increased cartilage content with incomplete ossification.[8] Therefore rib fractures are uncommon in children, and when present they generally indicate significant traumatic energy. Because the ribs do not absorb the kinetic energy, more energy is transferred to the internal organs. Pulmonary contusions are commonly present without rib fractures.

The smaller chest transmits breath sounds more readily. Even in cases of a large pneumothorax or effusion, the breath sounds may seem equal. Pediatric patients are more vulnerable to developing hypoxemia, as their basal metabolic rate is higher leading to greater oxygen consumption. Children also have a smaller functional residual capacity, which manifests as a rapid decline in oxygen saturation during endotracheal intubation, even when the patient has been preoxygenated by facemask. The trachea is also more compressible and narrower. Therefore children are more susceptible to profound respiratory distress with mucous plugging or aspiration of a small foreign body.

Children can compensate and maintain blood pressure with up to a 40% blood loss, and a critical situation may not become apparent until their blood loss is profound. Their cardiac contractility is fixed in early life; therefore heart rate must increase to increase cardiac output. However, in a frightened child, a normal heart rate is variable. Children have a relatively high body surface–to–volume ratio, allowing for a high rate of radiant cooling, and therefore pediatric patients can become hypothermic quickly, either outdoors or in the trauma bay.

Initial Resuscitation and Diagnosis

The initial care of all patients should follow the principles of Pediatric Advanced Life Support (PALS). First and foremost, the airway should be secured. The inability to maintain an airway or a Glasgow Coma Score ≤8 should prompt immediate orotracheal intubation and controlled ventilation. Patients with suspected cervical spine injuries or unknown cervical spine status should have manual in-line cervical stabilization during endotracheal intubation and a cervical collar placed promptly after endotracheal intubation. If an adequate airway cannot be established with

orotracheal intubation, then a surgical airway should be established. Once an airway has been established, ventilation should be assessed. The chest should be observed for symmetrical rise and fall. The right and left chest should be auscultated to ensure adequate airflow and the position of the endotracheal tube confirmed with a chest radiograph. Arterial oxygen saturation or pulse oximetry should be used to assess oxygenation. Arterial carbon dioxide or capnography may be used to assess ventilation. Life-threatening conditions such as airway compromise, tension pneumothorax, hemothorax, and cardiac tamponade should be identified immediately and treated (as described later). A child who loses vital signs in the trauma bay may require an emergent thoracotomy.

Circulation should be assessed by the pulse, heart rate, and capillary refill. In a warm, well child, the capillary refill should be ≤2 to 3 seconds. The radial, posterior tibial, and dorsalis pedis pulses can be palpated to assess peripheral circulation and heart rate. Blood pressure should be assessed with an appropriately sized cuff in order to yield an accurate value. Adequate intravenous access should be quickly established with two large-bore peripheral intravenous catheters. If peripheral access cannot be established, then a central line should be placed or intraosseoous access obtained. However, more volume can be given over a shorter period of time through a peripheral intravenous line than a central line, due to the resistance over the length of the central line. An initial intravascular or intraosseous isotonic saline bolus of 20 mL/kg should be administered. If the patient's vital signs do not improve, a second bolus should be administered, followed by transfusion of blood products to approximate whole blood.

Once the child's airway, breathing, and circulation have been addressed, the child should undergo a thorough physical examination to evaluate for injuries. The thoracic exam should include examining the patterns of bruises and lacerations to predict internal injuries. The chest should be palpated to look for rib tenderness or fractures. A chest radiograph should be used as the initial screening tool for blunt thoracic trauma.[9] Computed tomography (CT) can be an important tool in the diagnosis of blunt trauma, and it is certainly the gold standard for injury detection. However, in the pediatric patient, exposure to unnecessary radiation is a significant concern.[10] The routine use of CT scanning is therefore not justified unless there is adequate symptomatology to suggest a significant injury.[11] Most clinically useful information found on CT scan for chest trauma can be correlated with findings on chest radiograph. CT should be used selectively, particularly for the evaluation of an abnormal mediastinal silhouette on chest x-ray.[12] Exposure to radiation can be limited by lowering the radiation dose, avoiding redundant studies, limiting studies based on a risk/benefit profile, and using alternative technology such as MRI and ultrasonography.[13]

The role of ultrasound in the pediatric trauma bay is controversial and appears to be less useful than in adult trauma patients. The focused assessment with sonography for trauma (FAST) primarily examines abdominal injury, but ultrasound can be used to detect signs of pneumothorax and pathologic pericardial fluid. In one study, the sensitivity of FAST for detecting injuries requiring operation or blood transfusion was only 87%. The sensitivity and specificity for detecting pathologic free fluid were 50% and 85%, respectively.[14] The sensitivity of FAST is not sufficient to forego other imaging tests when there is clinical suspicion to warrant investigation.[14] However, FAST is still performed at some centers.

Chest Wall Injury

The elasticity of the ribs in small children protects against fractures, even in cases of severe injury. Therefore rib fractures should be considered a marker of exposure to significant traumatic energy. Isolated rib fractures without associated injuries are found in a minority of children. Rib fractures in children are associated with higher rates of brain injury, hemo/pneumothorax, and liver injury.[15] Higher rib fractures are not associated with great vessel injury in children, and in isolation they do not warrant aortography.[16,17] Lower fractures are associated with liver, spleen, and diaphragm injury.

The overwhelming majority of children 3 years and younger with rib fractures have been abused, and abused children tend to have more rib fractures than accidentally injured children. Therefore any young child who presents with rib fractures should raise a red flag for a nonaccidental trauma mechanism. However, accidentally injured children are more likely than abused children to have internal thoracic injuries (56% versus 13%). This is likely due to the difference in mechanism of injury. Abuse is usually performed over a longer duration of time from manual chest squeezing or a crush mechanism. Accidental trauma tends to be high energy and of short duration.[18]

In most cases, rib fractures are treated nonoperatively, although they do produce a great amount of pain, and often admission is required for pain control. The goal should be to encourage pulmonary toilet and prevent atelectasis and pneumonia. Nonsteroidal antiinflammatory medications as well as opioids and regional anesthetic techniques (nerve blockade) may all play a role in pain management. It is rare for children with isolated rib fractures to require ventilatory assistance. In rare cases, multiple ribs in a single area may be fractured and produce a *flail chest.* Specifically, this requires fractures of multiple contiguous ribs with at least 2 points of fracture per rib or fracture of the sternum or dislocation of rib heads. Flail chest results in paradoxical respiratory movement in which the thoracic wall over the flail segment collapses during inspiration, thereby impeding gas exchange.

The medial physis of the clavicle does not close until 23 to 25 years of age. Falls from trampolines are associated with fracture of the clavicle, and falls can lead to posterior sternoclavicular fracture-dislocations in children. This injury can be associated with dysphagia, dyspnea, and brachiocephalic compression. Children with clavicular dislocations should be evaluated for injury to the esophagus and great vessels.[19]

Sternal fractures, although rare, are usually associated with blunt traumatic injuries. They can result from motor vehicle crashes, flexion-compression injuries, or direct blows. They may be associated with cardiac injury. All patients with sternal bruising or fracture should be evaluated for cardiac contusion, and patients should have a careful examination and imaging of the spine.[20] Ultrasound has a high sensitivity and specificity in the diagnosis of sternal fractures.[21] Scapular fractures are uncommon in children, as a significant amount of force is required to fracture the scapula. A careful neurologic and vascular exam should be performed, as axillary artery and brachial plexus injuries may be present.

In rare cases of chest trauma, an intercostal hernia may form, resulting in lung herniation. Most hernias occur at a site of previous injury and are commonly seen at the anterior parasternal border because the cartilaginous junction to the sternum is

absent. Most are experienced after blunt trauma, particularly after multiple rib fractures or chondral costal dislocation. The hernia should be treated by direct surgical repair and may require mesh placement.[22,23] Thoracoscopic hernia repair has been described.[24]

Lung and Airway Injury

Pneumothorax (air in the pleural space) and hemothorax (blood in the pleural space) can both lead to respiratory compromise and subsequent cardiovascular collapse. Occult pneumothorax is the least severe of these entities and is defined as air in the pleural space seen on CT but not visible on chest radiographs. Occult pneumothorax can be safely observed and does not necessitate tube thoracostomy.[25] Minor pneumothorax produces mild clinical symptoms including tachypnea, distress, and decreased oxygen saturation. Pneumothorax may be suspected on physical exam when bruising or rib fractures are evident on the chest wall. Asymmetry in breath sounds or chest wall movement should also raise suspicion. Tension pneumothorax occurs when an injured tissue (either lung parenchyma or chest wall) forms a one-way valve, allowing air to enter the pleural space and preventing air from escaping. Tension pneumothorax results in major distress with distention of the affected side, displacement of mediastinal structures, and compromised venous return. Tracheal deviation may be seen with tension pneumothorax, as the tension in the air-filled side leads to compression of the healthy lung and deviation of the midline away from the side of the pneumothorax. Any patient with a suspected pneumothorax and signs of respiratory or cardiac decline should receive immediate needle decompression of the chest cavity. Needle decompression can be performed by placing a needle and catheter into the second intercostal space at the midclavicular line. Upon entering the pleural space, the clinician should hear an immediate rush of air. At this point, the needle should be removed but the catheter left in place while the patient is prepared for tube thoracostomy. The patient should be placed in the supine position with the arm in complete abduction. This position widens the intercostal spaces, facilitating placement of the tube. Tube thoracostomy should be performed by inserting an intercostal tube into the fifth or sixth intercostal space in the midaxillary or anterior axillary line. At this level, there is little risk of injury to the long thoracic nerve. A tube thoracostomy that is placed too low may inadvertently be placed below the diaphragm with resultant injury to the liver, spleen, or intestines. An adequately large tube should be placed to facilitate drainage of air, fluid, and blood. The tube should be connected to water seal drainage and suction to facilitate reexpansion of the lung (Fig. 120.1).

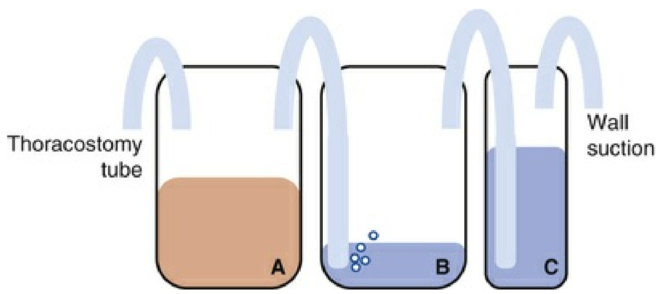

FIG. 120.1 Chest drainage system. The first chamber (A) connects directly to the thoracostomy tube and allows for drainage of fluid from the pleural space. The second chamber (B) creates a water seal, or one-way valve, that permits air to exit the pleural space during expiration but prevents air from returning during inspiration. The third chamber (C) regulates the amount of suction applied to the pleural cavity. This chamber connects to wall suction, but the height of the water column is what controls the amount of suction.

The majority of chest injuries resulting in pneumothorax or hemothorax require only a tube thoracostomy for successful management. The pulmonary circulation operates at a low arterial pressure and bleeding is slow from tears in the lung parenchyma. Hemostasis generally occurs as the lung reexpands. Removal of blood from the pleural space is necessary for several reasons: The lung may become entrapped as a hematoma expands or solidifies, or an empyema may develop in the nutrient-rich blood. In cases of ongoing hemorrhage, the blood loss should be quantified. Exsanguinating hemorrhage usually involves intercostal, hilar, or mediastinal vessels. When the output is greater than 20% to 30% of the child's blood volume or if the output exceeds 2 to 3 mL/kg/hr over the following 6 hours, then a thoracotomy should be performed.

If a massive air leak from the thoracostomy tube persists, injury to the trachea or bronchi is likely. This injury may require prompt intubation with fiberoptic bronchoscopy assistance. Appropriate ventilation and healing may be achieved by passing the endotracheal tube beyond the site of the airway injury. Unilateral intubation of the unaffected lung may also be used to aid healing or survival until the injury can be surgically repaired. The trachea and bronchi may be injured in both blunt and penetrating trauma. High-energy impact coupled with a closed glottis can produce elevated intraluminal pressures, causing rupture of the airway. The airway and bronchial tree may also be disrupted during violent deceleration or rapid crush injuries. The membranous portions of the trachea and bronchi are most susceptible to this type of injury. Airway disruption at any level can cause pneumomediastinum and eventual pneumothorax and be life threatening. Up to one-third in the first hour may be lethal.[26]

Pulmonary contusions most commonly occur after blunt trauma and are the result of high-energy application to the lung parenchyma. High-energy trauma to the chest causes twice as many lung contusions in children as in adults with significantly fewer rib fractures.[27] Pulmonary contusions may be present on the initial chest x-ray, but they often blossom over time. Contusion, hemorrhage, edema, and damage to the alveolar spaces can all occur and cause respiratory damage. However, few children will require intubation for pulmonary contusions alone. Pulmonary contusion in the pediatric population can lead to pneumonia (about 20%) but rarely causes acute respiratory distress syndrome (ARDS) as it does in an adult population.[28] Traumatic pneumatoceles can develop and are usually seen by 3 days after injury. Most resolve spontaneously within 3 to 4 months and do not require intervention.[29]

Traumatic Asphyxia

Traumatic asphyxia is a rare condition that can occur after severe compression to the

chest or abdomen, most commonly after a motor vehicle accident. During a compressive force, patients perform a Valsalva maneuver (holding their breath against a closed glottis, thereby increasing intrathoracic pressure). This increased intrathoracic pressure causes increased pressure in the innominate and jugular veins, leading to congestion in the venules and capillaries of the cervicofacial region. Sequelae include facial edema, cyanosis, conjunctival hemorrhage, face and chest petechiae, periorbital edema, respiratory distress, and altered mental status. Neurologic manifestations may include agitation, loss of consciousness, confusion, seizures, transient visual changes, or blindness. The majority of cases have a good prognosis, and although dramatic in presentation, the prognosis is good with most symptoms completely resolving.[30]

Cardiac Injuries

Cardiac injuries are rare in the pediatric population but are associated with a high mortality (40%). Most injuries are cardiac contusions (59%) after blunt trauma, but lacerations also occur (36%), most commonly after penetrating trauma. Cardiac injuries are associated with lung injury (46%), hemopneumothorax (37%), and rib fractures (26%). Cardiac arrest is rare (4%).[31]

Commotio cordis is a rare but life-threatening phenomenon seen in children after a blow to the chest. It leads to sudden cardiac arrest and is characterized by the absence of structural heart disease, pulmonary contusion, coronary artery abnormalities, or conduction system pathology. It occurs after a direct blow over the heart precisely timed to the phase of repolarization (15-30 milliseconds before the T-wave peak). Ventricular tachyarrhythmias ensue and can be treated with an automatic external defibrillator. It is commonly seen in young males in conjunction with sports-related injury, mainly basketball and football. Much attention has been focused on chest protectors and the availability of automatic external defibrillators at athletic events.[32]

Cardiac contusion with compromised cardiac function is rare in children but can be caused by blunt trauma. Children with bruising over the sternum or evidence of fracture should be evaluated for cardiac injury. Diagnosis of injury can be carried out with electrocardiography, echocardiography, and measurement of cardiac enzymes. Cardiac troponin is not found in skeletal muscle and should be measured, as total creatine kinase (CK) and CK-MB may be elevated from other muscle injury or inflammation. Transesophageal echocardiogram is the most sensitive indicator of cardiac injury. The most common manifestations are dysrhythmias and hypotension from decreased cardiac output. Patients should be treated with telemetry, intravenous access, oxygen, and analgesics. Dobutamine can be used to maintain cardiac output, provided the patient has been appropriately fluid resuscitated. Extreme injuries have been managed with an intraaortic balloon pump or extracorporeal membrane oxygenation (ECMO).[33] Cardiac ruptures following blunt impact are almost universally fatal.

Valvular injury after blunt trauma occurs infrequently. The aortic valve is most frequently injured, followed by the mitral and tricuspid valves. Valvular injury should be assessed with echocardiography, as many patients will be asymptomatic. However, cardiogenic shock can occur. The need for surgery is dictated by the extent and location of the injury, hemodynamic status of the patient, and presence of other

injuries. Approximately half of patients with an injury will require valve replacement.[34]

Most penetrating cardiac injuries occur in male patients in conjunction with stab wounds. Survival after cardiac laceration is less than 30%. Of those patients who survive to reach the trauma bay, mortality rates for a wound to the right atrium, left ventricle, right ventricle, and multiple chambers are 83%, 79%, 57%, and 100%, respectively.[35] Survival from stab wounds is much higher than from gunshot wounds, as a blast injury tends to be widely destructive to the cardiac parenchyma.[36]

Cardiac laceration can lead to pericardial tamponade, where blood escaping the heart through the wound fills the pericardial sac and leads to cardiac compromise. Cardiac tamponade should be suspected in an unstable patient with equal breath sounds and normal chest radiograph. The Beck triad includes muffled heart sounds, distended neck veins, and hypotension. This triad occurs in 90% of cases of cardiac tamponade. However, if the patient has lost a significant amount of blood from other sources, the neck veins may not be distended and it is often difficult to auscultate heart sounds over the noise of the trauma bay. All health care providers should maintain a high index of suspicion, and any penetrating injury to the chest must be considered a cardiac injury until proved otherwise. Ultrasound, if immediately available, can quickly determine the presence of a pericardial effusion. Patients with major hemodynamic instability and impending collapse should undergo prompt emergency room thoracotomy. Emergent pericardiocentesis has been abandoned as a management strategy, as the blood in the pericardial sac may clot rendering a false-negative result. The most frequent complications after cardiac repair include hypothermia, acidosis, and coagulopathy. Cardiac arrhythmias can be seen in patients after profound hypothermia.[36]

Aortic injury in children is exceedingly rare. Mechanisms of injury include high-energy deceleration, compression, or crush of the torso. Chest radiograph findings with blunt aortic injury commonly include prominent aortic knob, wide paratracheal stripe, or widened mediastinum on chest x-ray. Patients with a high-risk mechanism of injury and these chest radiograph findings should undergo CT examination (Fig. 120.2). Those patients too unstable to undergo CT scanning may also be evaluated with transesophageal echocardiography.[12]

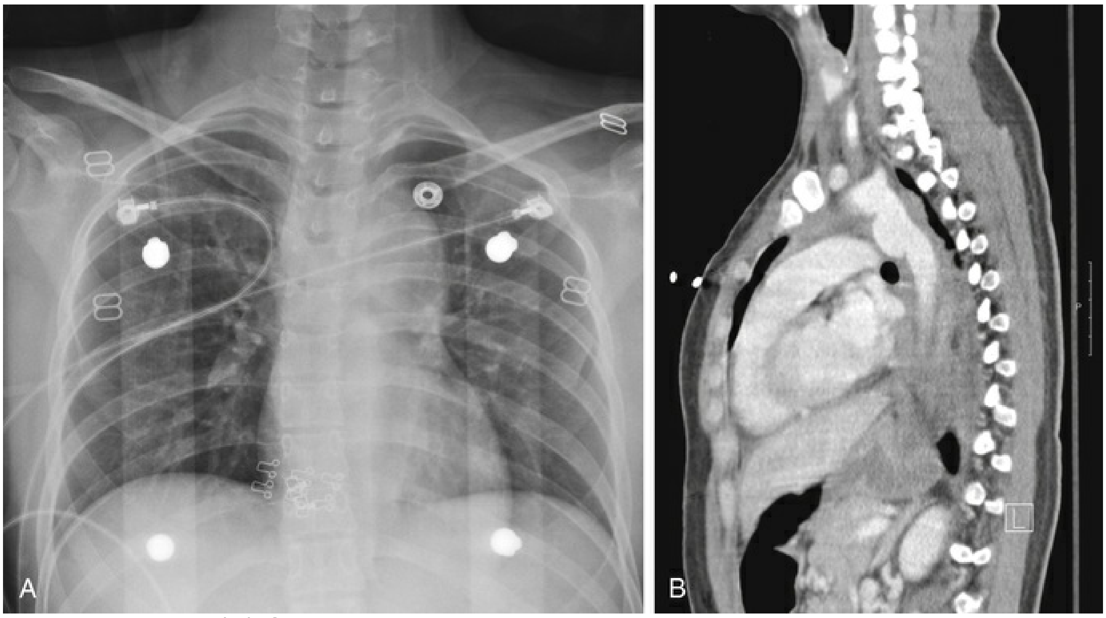

FIG. 120.2 (A) Chest radiograph demonstrating a prominent aortic knob, widened mediastinum, and right-sided tracheal deviation after blunt trauma. These findings are concerning for an aortic injury. (B) Subsequent CT scan showing an aortic tear causing a pseudoaneurysm.

Esophageal Injury

The esophagus is well protected in the center of the chest and it is rarely injured, even in penetrating trauma. High-energy trauma may create high intragastric pressure that can rupture the lower esophagus. Pneumomediastinum or pleural effusion after trauma should prompt an investigation for esophageal injury. Sepsis can occur rapidly with mediastinitis. Treatment in children differs from that of adults in that most adults require immediate primary repair. In the majority of cases, children are better served by a nonoperative approach based on adequate drainage of the affected space, parenteral nutrition, and antibiotics.[37] When an appropriate time for healing has passed and output from the drain has decreased, then a contrast esophagram should be obtained. Feeding should only be resumed after confirmation that the esophageal injury has completely healed.

Chylothorax

Traumatic chylothorax is rare in children but is usually seen after blunt trauma. It is associated with hyperextension of the spine and fractures of the spine or posterior ribs. Injury to the thoracic duct should be suspected when a pleural effusion is present on chest radiograph and an esophageal injury has been properly excluded from the diagnosis. Drainage of the fluid reveals a milky, white substance with triglyceride levels >110 mg/dl, the presence of chylomicrons, low cholesterol levels, and a predominance of lymphocytes. Most chylothoraces can be managed nonoperatively with chest tube drainage and total parenteral nutrition. Somatostatin and octreotide have been used to hasten closure of the injury. If the daily loss of chylous fluid exceeds 100 mL/year of age or if the defect fails to close with

nonoperative management, then surgical closure is indicated.[38] Children can become lymphopenic and lose IGG, thereby predisposing them to infection if the chylous drainage is excessive. They can also become malnourished.

Diaphragmatic Injury

Diaphragmatic rupture is a rare event in the pediatric population. Falls from heights and motor vehicle accidents are common mechanisms, but diaphragmatic injury also occurs with penetrating trauma. Differences in the distribution of blunt and penetrating trauma will vary with geographic location and the prevalence of violence among children. When it does occur, it is most commonly associated with other injuries. In many cases, the diagnosis can be made on chest radiograph. Pleural effusion, elevated hemidiaphragm, lower lobe collapse, and positioning of the nasogastric tube in the thorax are all findings that should prompt further investigation. Some hernias may be more difficult to detect and require CT examination. In either case, diagnosis requires a high index of suspicion. Left-sided rupture is more common, as the liver absorbs the energy on the right side. Associated injuries are common and can include any organ. Delay in diagnosis can lead to herniation and bowel incarceration. At laparotomy for trauma, both sides of the diaphragm should be carefully inspected. Repair of the diaphragm can be approached either via laparotomy or thoracotomy. It is often approached via laparotomy in the trauma setting, as this allows exploration of the other abdominal organs. Pneumonia is the most common postoperative complication after diaphragm repair.[39-41]

Conclusions

Thoracic trauma in the pediatric population is a major source of morbidity and mortality. Prompt intervention is required for life-threatening injuries and should follow the principles of managing the airway, breathing, and circulation. Lung and chest wall injuries are the most common and can primarily be managed with nonoperative intervention. Tube thoracostomy is the most common surgical intervention performed for thoracic trauma. Injuries to other organs in the chest are rare, but they are serious and require a high clinical index of suspicion. Prompt resuscitation and intervention minimize morbidity and mortality.

CHAPTER 121

Abdominal Trauma in Pediatric Critical Care

Susan F. McLean, Alan H. Tyroch

PEARLS

- In the initial resuscitation of trauma victims, the first priority remains the ABCs of ***a***irway, ***b***reathing, and ***c***irculation.
- When in doubt about the reliability of the airway or respiratory function, perform endotracheal intubation.
- The standard of care in treating hemodynamically stable children with hepatic or splenic injury is nonoperative observation.
- Patients who are hemodynamically stable may undergo further radiographic evaluation, whereas patients with evidence of an abdominal injury who remain clinically unstable after resuscitation with 40 mL/kg of fluid should be taken to the operating room for exploration.
- Splenic preservation is more important in younger children and is usually possible with nonoperative management or embolization.
- Vigilance and reexamination are necessary to detect a small bowel injury, which increases morbidity if missed for greater than 24 hours after trauma.

Trauma is the leading cause of morbidity and mortality in the pediatric age group. An estimated 1.5 million pediatric injuries occur each year, resulting in 500,000 hospitalizations and 20,000 deaths.[1] Thus trauma exceeds all other causes of death combined. Abdominal injuries are a marker of severe trauma, and evaluation of the child with an abdominal injury must include a thorough examination of the entire child. Management of pediatric trauma requires a multidisciplinary approach with emergency department physicians, critical care specialists, anesthesiologists, and surgeons working as a multidisciplinary team to provide prompt stabilization, assessment, and treatment. Performing the primary and secondary survey, ensuring a stable airway, instituting fluid resuscitation, and arriving at a decision as to the most appropriate management plan are the principal goals of the trauma team leader.

The majority of abdominal injuries in children are preventable. Health care

providers must work with the broader community to identify and alleviate causes of pediatric trauma. Education, public safety measures, and legislation will prevent many cases of pediatric injury. Nonaccidental abdominal trauma to children must be considered and, if suspected, must be reported to the appropriate agency. Developments in pediatric abdominal trauma include the use of imaging modalities such as focused abdominal sonography for trauma (FAST) and embolization of solid organ injuries, which allows for increased utilization of nonoperative management. Laparoscopy can be applied in select scenarios. As part of disaster preparedness, clinicians providing trauma care for children should have an awareness of wartime and mass casualty injury management.

Mechanisms and Patterns of Injury

The severity and pattern of abdominal injury correlate with the mechanism of injury. Blunt injury accounts for 90% of abdominal trauma in children. The most common mechanisms are motor vehicle collisions, automobile versus pedestrian crashes, falls, bicycle crashes, and nonaccidental trauma. In pediatric blunt abdominal trauma, solid viscus organs such as the liver, spleen, and kidney are more frequently injured than hollow viscus organs. Children suffering lap belt injury, handlebar injury, or kicks may suffer small bowel perforation. Children struck by motor vehicles can have a pattern of head injury, intraabdominal or intrathoracic injury, and a femur fracture (Waddell triad). In addition, urban violence and the high prevalence of firearms result in penetrating abdominal injuries in children. Although the mechanism of injury may correlate with the extent of injury, ongoing clinical assessment is a more sensitive indicator of the extent of blood loss and hemodynamic instability, and it determines the resuscitation and management of the child with an abdominal injury.

Penetrating Abdominal Trauma

Penetrating abdominal injuries are most commonly caused by firearm use or stabbings. In children, abdominal gunshot wounds result in more severe injuries than stab wounds because of the increased energy delivered by firearms, particularly shotguns and assault rifles.[2] Significant intraperitoneal injuries are present in most children who sustain gunshot wounds, suggesting the need for abdominal exploration in all gunshot victims. There is a trend toward selective exploration of penetrating injuries in adults. For example, computed tomography has been used successfully to determine the application of selective laparotomy in penetrating torso trauma.[3] However, most trauma centers continue to perform laparotomy on most patients with gunshot wounds to the abdomen. Abdominal stab wounds that penetrate the transversalis fascia are at high risk of intraabdominal injury. Expectant observation of stab wounds in children should rarely be applied because the true extent of injury is not always appreciated on local exploration.

Recreational and Sports Injury

Specific recreational activities commonly practiced by children, such as bicycling, all-terrain vehicle (ATV) use, skiing, snowboarding, and horseback riding, result in

predictable injury patterns that guide evaluation. Snowboard injuries are increasing and include abdominal injuries in 25% of cases.[4] At a level I pediatric trauma center in the United States, 213 cases of pediatric snowboarding injury were admitted over 7 years. Thirty-nine patients had an injury involving the thorax or abdomen, with almost half being abdominal. The spleen was the most commonly injured organ. Male gender and age ≤14 years were associated with a significant increase in abdominal injury. Upper extremity trauma was significantly associated with abdominal or pelvic trauma. ATV crashes produce a particularly damaging pattern of injury as the ATV has the weight of a car and the lack of protection of a motorcycle. This results in a combination of an ejection and rollover mechanism of injury with the worst of both. The majority of deaths involve head and spine injuries. Lack of helmet use is associated with a higher mortality. A retrospective study of trauma admissions to a level I pediatric trauma center of 163 pediatric ATV crashes showed that almost two-thirds of patients did not wear helmets.[5] Of those that did, helmet use was significantly associated with a lower incidence of injury to the head and neck.[5]

ATV abdominal injuries include crush injuries to liver, spleen, and kidney. Child drivers are more susceptible to crash, and it is alarming that child-sized ATVs are in production. Even where laws restrict ATV use by children, they are frequently injured and have a high rate of missed injuries.[6] Blunt impalement on a bicycle handlebar can result in a predictable pattern of injury to bowel, mesentery, or pancreas.

Wartime Trauma

Children can also be victims of wartime trauma causing abdominal and other injuries. Modern warfare is often conducted in urban areas with a civilian population present and the frequent involvement of children. Additionally, medical infrastructure is disrupted in a war zone and many residents suffer malnutrition and infections, which makes them more debilitated in the face of a new injury. Military high-energy rifles cause penetrating wounds in which the pressure wave of the projectile results in a cone of tissue destruction. In abdominal injuries, this necessitates wide debridement of soft tissues, and a second-look laparotomy is often required to detect evolving intestinal necrosis. It is common for children to suffer blast and fragmentation injuries from land mines, bombs, indirect fire weapons (rockets and mortars), improvised explosive devices, and suicide bombings.[7] Land mines and air-delivered cluster bomblets are particularly insidious because their interesting colors and shapes attract children's curiosity. Wounds include pressure wave blunt injury, shrapnel penetration, and burns. These injuries in children often require a damage-control laparotomy, wide debridement of soft tissues, temporary abdominal closure, and multiple operations. Vacuum-assisted wound dressings are particularly useful.[8]

Evaluation and Resuscitation

Evaluation and resuscitation occur simultaneously when a child presents with an abdominal injury. The Advanced Trauma Life Support (ATLS) guidelines developed by the American College of Surgeons should be followed. The primary survey

includes stabilization of the cervical spine while evaluating for airway patency, function of breathing, and adequacy of circulation (the ABCs). Prompt endotracheal intubation should occur in any patient in whom the stability of these functions is in doubt. Intravenous access in the small child can be particularly challenging, and skilled personnel should be employed. If peripheral venous access is unsuccessful after two attempts in a hemodynamically unstable child, an intraosseous line should be attempted. Basic neurologic function is assessed. The patient must be completely exposed for examination and then covered with blankets to maintain body temperature. Children are more susceptible to heat loss and dehydration because of their greater surface area/mass ratio.

Physical Examination

Abdominal examination includes observation of external signs, then palpation for tenderness, distension, or firmness. Children swallow a large amount of air when they cry, and gastric distension may require orogastric tube or nasogastric tube decompression. Upper quadrant ecchymosis, tenderness, and associated rib fractures suggest the presence of liver or spleen injury. Midabdominal ecchymosis from a seat belt suggests the possibility of a small bowel injury. Stability of the pelvis is assessed with lateral and axial manual compression of the pelvic ring. Extraperitoneal bladder ruptures may cause localized suprapubic tenderness, whereas an intraperitoneal bladder rupture may present as generalized abdominal distension. Injuries near the abdomen may also be associated with intraabdominal injury. In a mixed adult/pediatric study of patients admitted to seven trauma centers in the United States over a 6-year period, patients with Chance fractures (horizontal fracture through the vertebra) of the thoracolumbar spine were reviewed. Of the 79 patients reviewed, one-third had an intraabdominal injury; hollow viscus injuries were the most common and were found in 22% of patients. Twenty-five percent of patients had a laparotomy; abdominal wall contusions were strongly associated with hollow viscus injury and need for laparotomy. Of 20 patients with abdominal wall contusion and Chance fractures, 85% had an intraabdominal injury and 70% required laparotomy.[9]

Laboratory Tests

Laboratory examination including complete blood counts, serum chemistries, and urinalysis should be obtained on all trauma patients. Additional studies, such as liver function tests and pancreatic enzymes, are indicated in certain injuries. Elevated transaminase levels suggest nonspecific parenchymal liver injury, whereas elevated amylase and lipase levels suggest a pancreatic injury. A base deficit greater than 6 mEq/L is a strong indicator of intraabdominal injury in blunt trauma. Hematuria is associated with intraabdominal injury and renal injury. Urinalysis demonstrating more than five red blood cells per high-power field combined with clinical assessment accurately predicts intraabdominal injury.

Radiographic Assessment

Prompt plain radiographs of the chest and pelvis should be obtained during the

initial assessment after blunt trauma. Patients who are hemodynamically stable may undergo further radiographic evaluation, whereas patients with evidence of an abdominal injury who remain clinically unstable after resuscitation with 40 mL/kg of fluid should be taken to the operating room for laparotomy.

Computed Tomography

Computed tomography with intravenous contrast (oral contrast is not routinely needed) is the procedure of choice for definitive radiographic assessment after blunt abdominal trauma in children. Clinical impression remains the most sensitive indicator of the need for computed tomography. Computed tomography can be used to identify hepatic, splenic, intestinal, pancreatic, renal, and bladder injuries in children and can even detect intestinal and mesenteric injury with sensitivities of 94% and 96%, respectively.[10] Findings on computed tomography suggestive of intestinal injury are unexplained free fluid without solid organ disruption, abnormal distribution of bowel loops, contrast extravasation, and contrast enhancement of intestinal wall.[11] The Organ Injury Scaling Committee of the American Association for the Surgery of Trauma has developed a grading system to estimate the extent of abdominal injury.[12,13] Short of operative exploration, computed tomography is the most accurate method used to grade the extent of injury. Concern over the use of abdominal CT scan and radiation exposure in children has led centers to reexamine the use of CT scan to evaluate blunt abdominal trauma and to try to make prediction rules for when CT scanning will be most helpful. A retrospective study of 571 pediatric patients at two Canadian level I pediatric trauma centers admitted after blunt abdominal trauma sought to correlate clinical parameters such as mechanism of injury, as well as radiologic and laboratory analysis variables that might predict injuries seen on CT scan. Injuries results were classified as “notable” or “clinically important” if the injures involved an Abbreviated Injury Scale (AIS) ≥3 injury or if the injury required surgery. Four hundred and forty-one (77%) of the children had an abdominal CT scan. Thirty-seven percent had a notable injury, and 18% had a clinically important injury. Most injuries were solid organ; only 2% were hollow viscus injuries. Factors significantly associated with notable abdominal injury included abdominal exam finding of pain or tenderness, hematuria, and elevated serum alanine aminotransferase (ALT). Factors that were significantly associated with clinically important injuries were low hematocrit and hematuria.[14]

If significant abdominal trauma was suspected, a CT scan was an excellent way to diagnose injury. Traditional signs on CT scan of small intestinal injury are free fluid, extravasation of enteric contrast, pneumoperitoneum, small bowel wall enhancement with intravenous contrast, or paucity of contrast in the intestinal wall. Newer 64-slice CT scans can identify signs of small intestinal injury, even though these may be indirect. A retrospective study of trauma patients suspected of abdominal injury who had a laparotomy demonstrating intestinal injury or mesenteric injury showed that there were no false-negative studies using the 64-slice computed tomography. Free fluid was seen all CT scans. Eighty-eight percent of patients had one finding in addition to free fluid. Findings associated with bowel or mesenteric injury on CT scan were free fluid, bowel wall thickening, mesenteric or bowel wall hematoma, active mesenteric bleeding, mesenteric stranding, pneumoperitoneum, or contrast extravasation. The most common finding besides free fluid was bowel wall thickening.[15]

Sonography

FAST is a rapid, noninvasive, and portable method to evaluate the abdomen. Various reports note that sonography for abdominal trauma has a sensitivity of 55% to 86% and a specificity of 95% to 98%.[16-18] Sonography accurately identifies intraperitoneal free fluid, but it does not accurately identify the source of that fluid. Sonography is comparable to diagnostic peritoneal lavage (DPL) as a method for detecting free peritoneal fluid, but it is noninvasive. However, it does not supplant computed tomography in its ability to define the specific nature and extent of abdominal injury.

Additional Assessment Tools

Diagnostic Peritoneal Lavage

Refinement in the nonoperative management of pediatric abdominal trauma makes DPL unnecessary in stable patients, because the presence of free intraperitoneal blood is not an absolute indication for surgery in children. In addition, performing a DPL can be difficult in small children due to the decreased domain of the smaller abdomen. However, DPL is a useful triage tool for selectively applying laparotomy for blunt intestinal trauma in children. In the rare event that a DPL is performed in a child, the procedure is the same as in adults except that the amount of warm crystalloid instilled into the abdominal cavity is less (10 mL/kg). In one series, the cell count, amylase activity, and particulate matter in the DPL specimen were able to identify small bowel perforation with a sensitivity of 100%.[19]

Diagnostic Laparoscopy

Diagnostic laparoscopic evaluation has been suggested as a safe and effective modality for evaluating the abdomen in the stable patient after penetrating trauma. Diaphragmatic injuries can be diagnosed and repaired laparoscopically.[20] Thoracoscopy in hemodynamically stable penetrating-trauma patients can be used to avoid nontherapeutic laparotomy by ruling out penetration of the abdominal cavity and can identify thoracic and diaphragmatic injuries.

Management of Specific Abdominal Injuries

Children often demonstrate hemodynamic stability in the face of significant hemorrhagic loss, until their capacity for compensatory vasoconstriction is surpassed. Although fluid resuscitation and blood transfusion are far and away the primary therapy, a select few children may require inotropic support after major trauma. Frequent serial abdominal examinations are performed to determine the need for surgical exploration for a missed hollow viscus injury. Operative intervention should not be delayed, because hypotension and decreased cerebral perfusion pressure worsen morbidity and mortality. Although abdominal compartment syndrome has a low reported incidence of 0.6% to 4.7% in critically injured children, it will only be detected through a high index of suspicion and frequent measurement.[21] In stable patients, early enteric feeding maintains immune function and shifts the patient to a more anabolic balance.

Nonoperative Management of Solid Organ Injuries

The standard of care in treating hemodynamically stable children with hepatic or splenic injury is nonoperative observation. Management of these injuries varies widely between adult and pediatric facilities, and splenectomy can be avoided if a child is taken to a facility that utilizes this nonoperative strategy. The American Pediatric Surgical Association Trauma Committee has proposed guidelines for care based on radiographic severity of injury (Table 121.1). Although observation has traditionally taken place in the intensive care unit, there is evidence that observation on a ward is safe.[22]

TABLE 121.1

Proposed Guidelines for Resource Utilization in Children With Isolated Spleen or Liver Injury

CT Grade	I	II	III	IV
ICU stay (days)	None	None	None	1
Hospital stay (days)	2	3	4	5
Predischarge imaging	None	None	None	None
Postdischarge imaging	None	None	None	None
Activity restriction (weeks)[a]	3	4	5	6

[a]Return to full contact, competitive sports (eg, football, wrestling, hockey, lacrosse, mountain climbing) should be at the discretion of the individual pediatric trauma surgeon. The proposed guidelines for return to unrestricted activity include “normal” age-appropriate activities.

Data from Stylianos S, APSA Trauma Committee. Evidence-based guidelines for resource utilization in children with isolated spleen or liver injury. J Pediatr Surg. 2000;35:164-169.

Embolization of Solid Organ Injuries

Computed tomography can identify active extravasation from splenic and hepatic injuries. Angiography is able to map out the specific site of hemorrhage, and embolization can be used to selectively occlude the bleeding vessel. This therapy reduces the need for transfusion and avoids the need for laparotomy. Nonselective embolization of the main splenic artery has also been shown to reduce bleeding (Fig. 121.1). Angiography should be reserved for children with active extravasation who are hemodynamically stable. Unstable patients with solid organ injury require laparotomy.

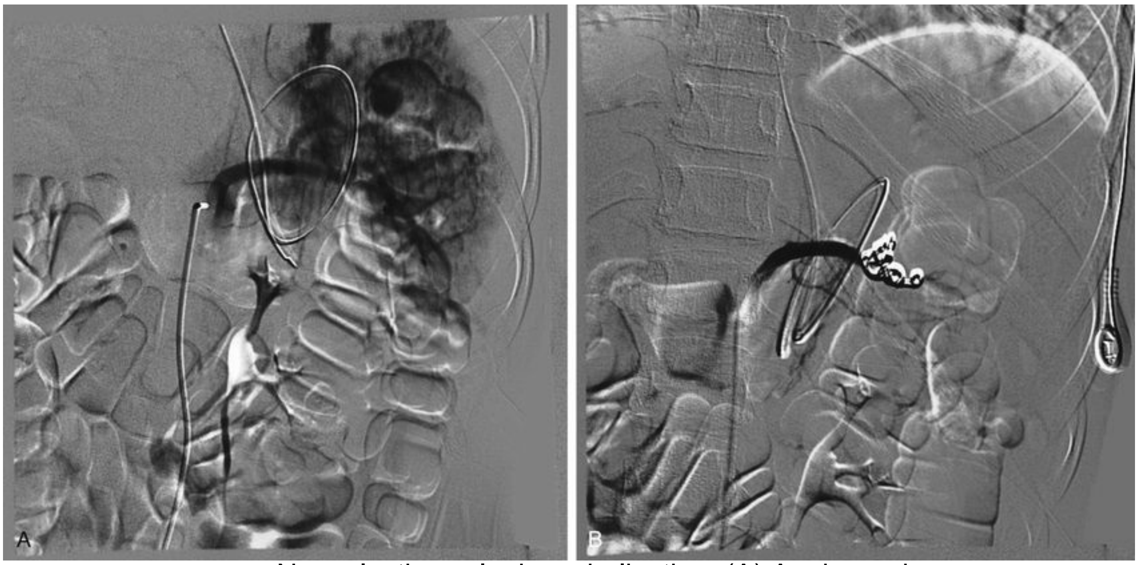

FIG. 121.1 Nonselective splenic embolization. (A) Angiography demonstrates splenic injury with active extravasation of blood. (B) Postembolization image demonstrating coil in splenic artery and resolution of hemorrhage.

Injury to the Spleen

The spleen is the most commonly injured abdominal organ in blunt trauma. Treatment of splenic injury has evolved from routine splenectomy to a strategy of nonoperative management that is successful greater than 90% of the time.[23] Splenic injuries are most often caused by a direct blow to the left upper quadrant and manifest as localized tenderness, abrasion, or ecchymosis. Splenic injury is graded by computed tomography (Figs. 121.2 and 121.3, Table 121.2). Operative intervention for splenic trauma usually results in splenectomy. For this reason, nonoperative management should be attempted in stable children, regardless of the severity of injury. Angiography and embolization of splenic vessels can control hemorrhage without laparotomy. If a stable child with a splenic injury requires laparotomy for injury to another organ, splenorrhaphy and autotransfusion increase splenic salvage, which reduces risk of infection.[24] At pediatric trauma centers, operating on a child with an isolated splenic injury is rare. The indications for operative intervention are generally limited to persistent hypotension, greater than 50% blood volume replacement, or additional life-threatening abdominal injuries.

FIG. 121.2 CT scan of a patient with a grade IV splenic laceration.

FIG. 121.3 CT scan of a patient with a grade IV splenic laceration demonstrating free fluid around the tip of the spleen.

TABLE 121.2

Abdominal Organ Injury Computed Tomography Grading Scales[a]

Injury	Grade I	Grade II	Grade III	Grade IV	Grade V	Grade VI
Splenic hematoma	Subcapsular, <10% surface area	Subcapsular, 10%-50% surface; intraparenchymal, <5 cm diameter	Subcapsular, >50% surface or expanding; intraparenchymal >5 cm or expanding;			

			ruptured			
Splenic laceration	<1 cm depth	1-3 cm depth	>3 cm depth or involving vessel	Segmental vessel >25% devascularization	Shattered spleen	
Splenic vascular					Hilar injury 100% devascularization	
Hepatic hematoma	Subcapsular, <10% surface area	Subcapsular, 10%-50% surface; intraparenchymal, <10 cm diameter	Subcapsular, >50% surface or expanding; intraparenchymal >10 cm or expanding; ruptured			
Hepatic laceration	Capsular tear, <1 cm depth	1-3 cm depth, <10 cm length	>3 cm depth	Disruption 25%-75% of lobe or 1-3 Couinaud segments in lobe	Disruption >75% lobe or >3 Couinaud segments in lobe	
Hepatic vascular					Injury to cava or hepatic vein	Avulsion
Duodenum hematoma	Single portion	>1 portion				
Duodenum laceration	Partial thickness	<50% circumference	50%-75% circumference second portion	>75% circumference second portion, ampulla, or common bile duct	Disruption duodenopancreatic complex	
Duodenal vascular					Devascularization of duodenum	
Pancreas hematoma	Minor contusion	Major contusion				
Pancreas laceration	Superficial	Major	Distal transaction or duct injury	Proximal transaction or ampulla injury	Massive disruption of head	
Kidney contusion	Hematuria					
Kidney hematoma	Subcapsular, nonexpanding	Confined to retroperitoneum				
Kidney laceration		<1 cm depth	>1 cm depth	Through cortex, medulla, and collecting system	Shattered kidney	
Kidney vascular					Avulsion	

[a]Add one grade for multiple injuries up to grade III.

From Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. J Trauma. 1990;30:1427-1429; Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. J Trauma. 1989;29:1664-1666.

Nonoperative management consists of large-bore venous access for fluid resuscitation, intensive care unit monitoring, frequent hematocrit values, serial physical examinations, and bed rest. Recommendations from the American Pediatric Surgery Association Trauma Committee indicate only short periods of observation are necessary.[22] This abbreviated observation, 1 day of bed rest for grade I and grade II injuries and 2 days of bed rest for higher-grade injuries, has been validated to be safe.[25]

Injury to the Liver

The liver is the second most commonly injured organ in blunt abdominal trauma. Liver injuries are associated with high mortality and may require surgical correction of injuries to the hepatic veins or vena cava. Liver injuries in stable patients can usually be managed nonoperatively. Ecchymosis, bruising, or abrasions over the right upper quadrant suggest significant injury. Liver injury is graded by appearance

on computed tomography (see Table 121.2). However, the clinical course of the patient, not the appearance on computed tomography, should determine treatment (Figs. 121.4 and 121.5). Elevated serum transaminase concentrations are associated with liver trauma and other intraabdominal injury.[26] Late complications of liver injuries include bile peritonitis, abscess formation, hemorrhage, and hematobilia. Operative treatment may be required for major hepatic trauma associated with hepatic vein or retrohepatic caval injuries. Definitive repair is often not possible at the time of initial exploration, necessitating damage-control surgery with packing, maintaining an open abdomen, further resuscitation, stabilization, and repeat laparotomy. Select patients with ongoing bleeding from a hepatic injury can be stabilized with embolization of hepatic blood vessels.

FIG. 121.4 CT scan of a patient with a grade II hepatic hematoma.

FIG. 121.5 CT scan of a patient with a grade IV hepatic laceration.

Injury to the Small Bowel

Bowel injuries resulting from blunt trauma are relatively rare. However, a high index of suspicion must be maintained to avoid a delayed diagnosis, which is more

common in children. The incidence of small bowel injury increases with increasing number of other organs injured.[27] The mechanisms of injury associated with blunt bowel trauma include motor vehicle/pedestrian collisions, handlebar injuries, lap belt injuries, and child abuse. Deceleration injuries in children restrained with a lap belt may occur as a constellation that includes intestinal injury, abdominal wall ecchymosis, and flexion-distraction injury (Chance fracture) to the lumbar spine (Fig. 121.6).[9] Intestinal injuries include bowel disruption, mesenteric avulsion, and bowel wall contusion (Fig. 121.7). Areas of the small bowel particularly prone to injury are the points of retroperitoneal fixation, such as the proximal jejunum at the ligament of Treitz or the terminal ileum near the junction with the cecum. A perforation may be present even without free air or significant spillage of succus on DPL. Delayed perforations may occur as a result of mesenteric disruptions and subsequent bowel necrosis. In some instances, a prolonged ileus that fails to resolve may be the only evidence of intestinal injury.

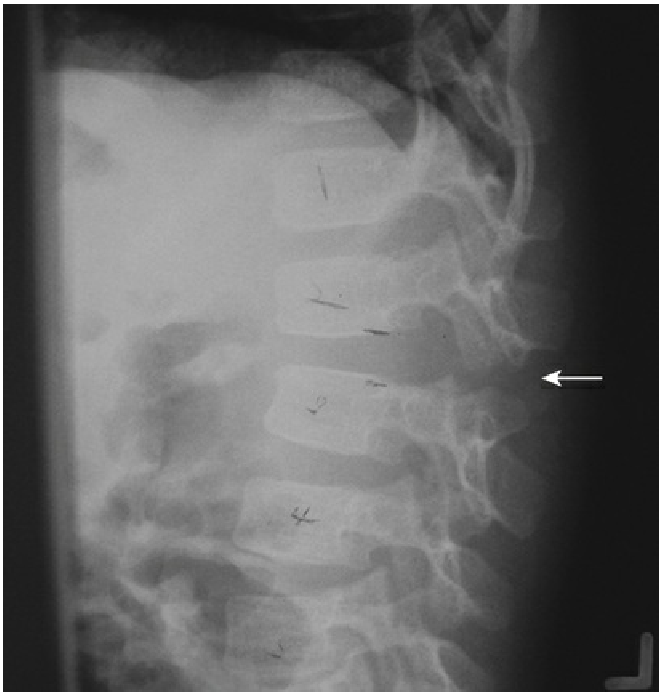

FIG. 121.6 Plain lateral lumbar spine radiograph. *Arrow* indicates distraction injury to posterior spine secondary to lap belt injury.

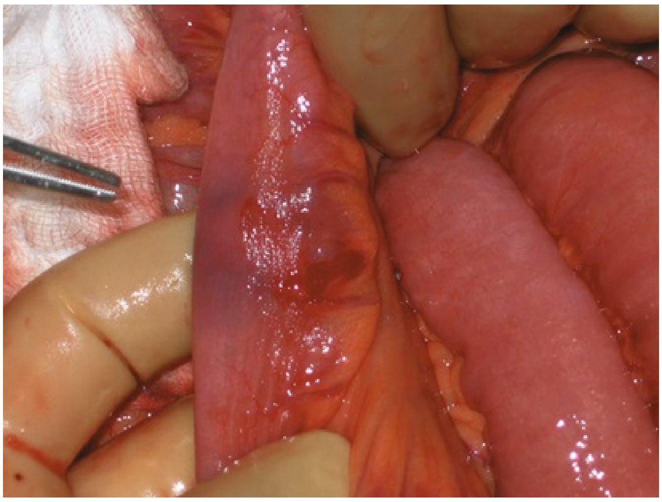

FIG. 121.7 Small bowel contusion after blast injury.

The mechanism of injury and abdominal wall ecchymosis can suggest the diagnosis of intestinal injury. Abdominal tenderness may be present on physical examination. Findings on computed tomography consistent with small bowel injury are free fluid, contrast extravasation, focal bowel thickening, pneumoperitoneum, and fat stranding or fluid in the mesentery.[28] Once diagnosed, bowel injuries are treated by laparotomy. Excision of injury and primary anastomosis to reestablish gastrointestinal continuity are usually possible. Morbidity and mortality are not increased if the delay in diagnosis is less than 24 hours.[19]

Injury to the Duodenum

Duodenal injuries are rare in children but occur more commonly than in adults. Children may have localized right upper quadrant tenderness, but the presentation may be subtle. The majority of duodenal injuries in children result in a duodenal hematoma without disruption of the lumen. When there is perforation, computed tomography demonstrates extraluminal gas or oral contrast extravasation in the right anterior pararenal space. Thickening of the duodenal wall is seen when a duodenal hematoma is present. Duodenal injuries are classified from grade I to V based on severity (see Table 121.2). The majority of pediatric duodenal injuries are grades I and II. Overall, mortality is 18% for patients with duodenal injuries. For grade I lesions, the mortality is 8%, with associated injuries as the usual cause of death.

A duodenal hematoma is treated with observation and parenteral hyperalimentation. Resolution generally occurs in 2 to 4 weeks. In some cases of duodenal hematoma, placement of a nasojejunal tube will allow enteral feeding distal to the point of obstruction. Repair of full-thickness duodenal injury may require duodenorrhaphy, pyloric exclusion, duodenoduodenostomy, duodenojejunostomy, pancreaticoduodenectomy, or simple drainage (Fig. 121.8). The majority of injuries are treated with debridement and primary closure with drainage. Pyloric exclusion is recommended for complex duodenal injuries. Duodenostomy and regional drains are useful. In children, pancreaticoduodenectomy is rarely required to treat a duodenal injury.

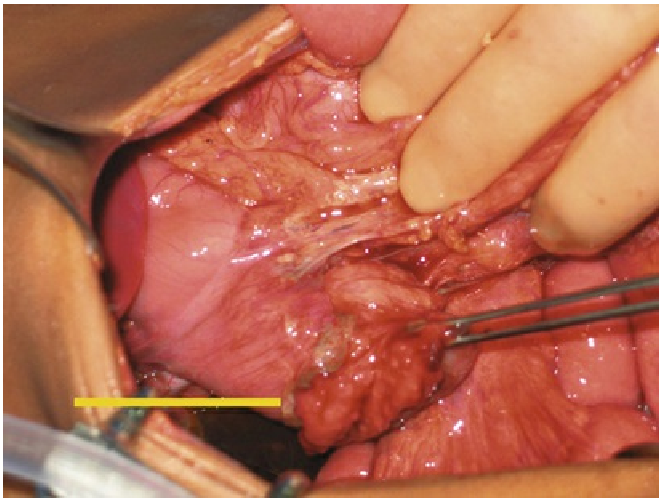

FIG. 121.8 Grade III duodenal laceration blowout injury after fall onto a handrail.

Injury to the Pancreas

Injuries to the pancreas may require operative intervention depending on severity of injury and integrity of the pancreatic duct (see Table 121.2). Upper abdominal tenderness, hyperamylasemia, edema of the gland, and unexplained fluid in the lesser sac on computed tomography suggest pancreatic injury. Handlebar injury, lap belt injury, direct blow to the abdomen, and motor vehicle crash are the most common mechanisms (Fig. 121.9). When the gland is fractured, this generally occurs where it crosses the vertebral column (Fig. 121.10). Pancreatic transection is best treated by early distal pancreatectomy and drainage. When the main pancreatic duct is intact, nonoperative treatment with an extended course of bowel rest and parenteral nutrition should be attempted. Devascularization of the pancreas and duodenum in blunt abdominal trauma is rare in children. When it does occur, laparotomy, pyloric exclusion, drainage, and repeated debridement with an open abdomen may be required. After pancreatic injury, pseudocysts may develop and require internal or external drainage after maturation. Operative drainage of a pseudocyst to the stomach or a roux-en-Y loop of intestine should be delayed for at least six weeks until the pseudocyst wall is mature. An infected pseudocyst may require urgent percutaneous drainage. Magnetic resonance cholangiopancreatography or endoscopic retrograde cholangiopancreatography is useful to diagnose pancreatic duct disruption, and a pancreatic stent can be placed across the disrupted duct, which potentially prevents pseudocyst formation[29] (Fig. 121.11).

FIG. 121.9 Handlebar injury in a patient who required distal pancreatectomy.

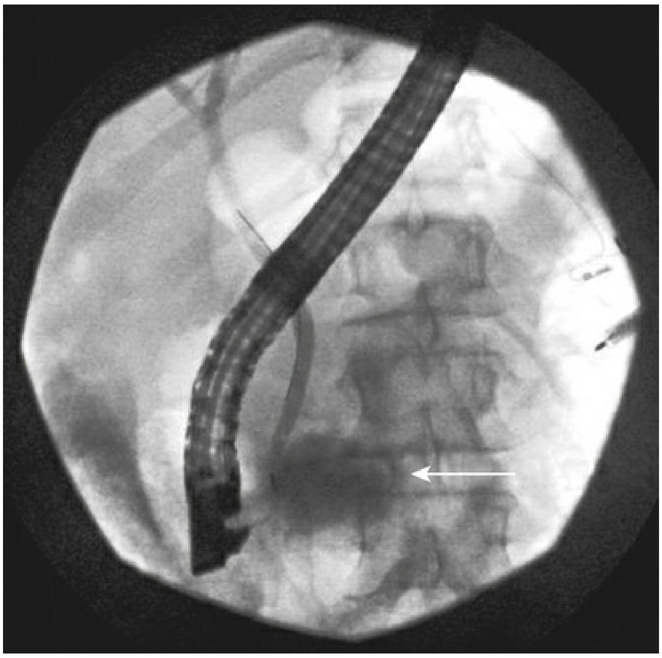

FIG. 121.11 Endoscopic retrograde cholangiopancreatography demonstrates pancreatic duct leak after a kick to the abdomen.

Blunt Abdominal Aortic Injury

The majority of aortic injuries after blunt trauma are in the chest, with only 6% in the abdomen.[30] Pedestrians struck by a motor vehicle and unrestrained passengers are more likely to have thoracic injuries, whereas passengers with lap belt injuries are more likely to injure the abdominal aorta.[31] Injury to the renal artery or mesenteric artery is more common than aortic injury.[32] Computed tomographic angiography is capable of providing a definitive diagnosis; however, angiography may be required in some children. Aortic injuries include contusion, intimal dissection, and complete disruption. The most frequent site of disruption is at the inferior mesenteric artery or the renal arteries. Patients present with diminished or absent distal lower extremity pulses. Neurologic deficits may result from aortic compromise. Associated injuries are present in 65% of cases. When blunt abdominal aortic injury is recognized early, surgical intervention can dramatically lower mortality. A pseudoaneurysm can develop as a late complication. Major abdominal venous injuries resulting from blunt trauma are usually fatal.

Renal Trauma

Renal injury rarely occurs as an isolated injury. Findings suggestive of renal injury include flank tenderness, flank or abdominal mass, or ecchymosis. Hematuria, either gross or microscopic, is the best indicator of serious renal injury. However, serious injury, especially renal pedicle injuries, may be present even without hematuria. In hemodynamically stable patients, computed tomography with intravenous contrast allows for an accurate diagnosis of renal injury and function (Fig. 121.12). Sonography also provides an accurate diagnosis of extrarenal fluid collections.[33] Renal trauma can result in a hematoma, laceration, or vascular injury (see Table 121.2). Children who are hemodynamically stable may be safely managed

nonoperatively. Angiography with embolization can control hemorrhage when contrast extravasation is seen on computed tomography.[34] Exploration is warranted in children who are hemodynamically unstable, have an expanding hematoma, or have an associated abdominal injury necessitating exploration. In unstable patients, nephrectomy is the safest choice; however, the surgeon must ensure that the contralateral kidney is present before proceeding. Renal repair or partial nephrectomy is possible in select cases (Fig. 121.13). Isolated urinary extravasation is not an indication for emergent exploration, but delayed operation or percutaneous drainage may be required for persistent extravasation or infection. If urinary extravasation is present, antibiotics should be administered. Patients with extravasation and devascularized segments on computed tomography have a higher incidence of delayed complications. Observation and bed rest usually result in excellent outcome, even with deep parenchymal lacerations associated with urinary extravasation. Patients with gross hematuria are kept on bed rest until the urine is grossly clear. Reevaluation is necessary for persistent hematuria, tenderness, or mass. All patients with renal injuries, regardless of severity, should be monitored for the delayed onset of hypertension. A captopril-furosemide technetium-99m diethylenetriamine pentaacetic acid (DTPA) renal scan is used to verify function after injury (Fig. 121.14).

FIG. 121.12 CT scan of a patient with a grade IV renal laceration and vascular injury.

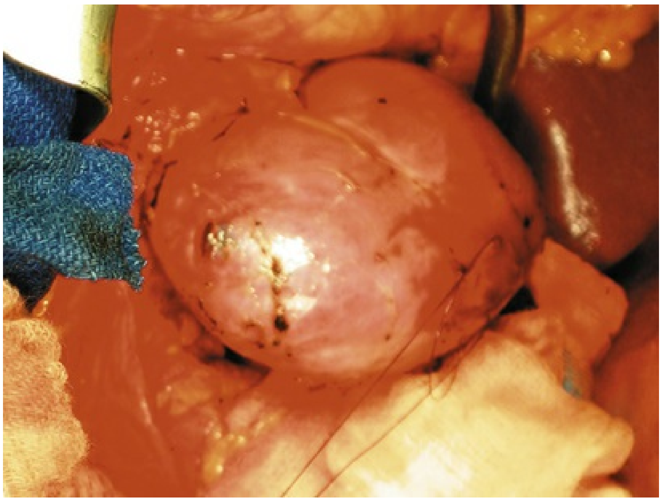

FIG. 121.13 Repair of a grade II renal laceration after penetrating trauma.

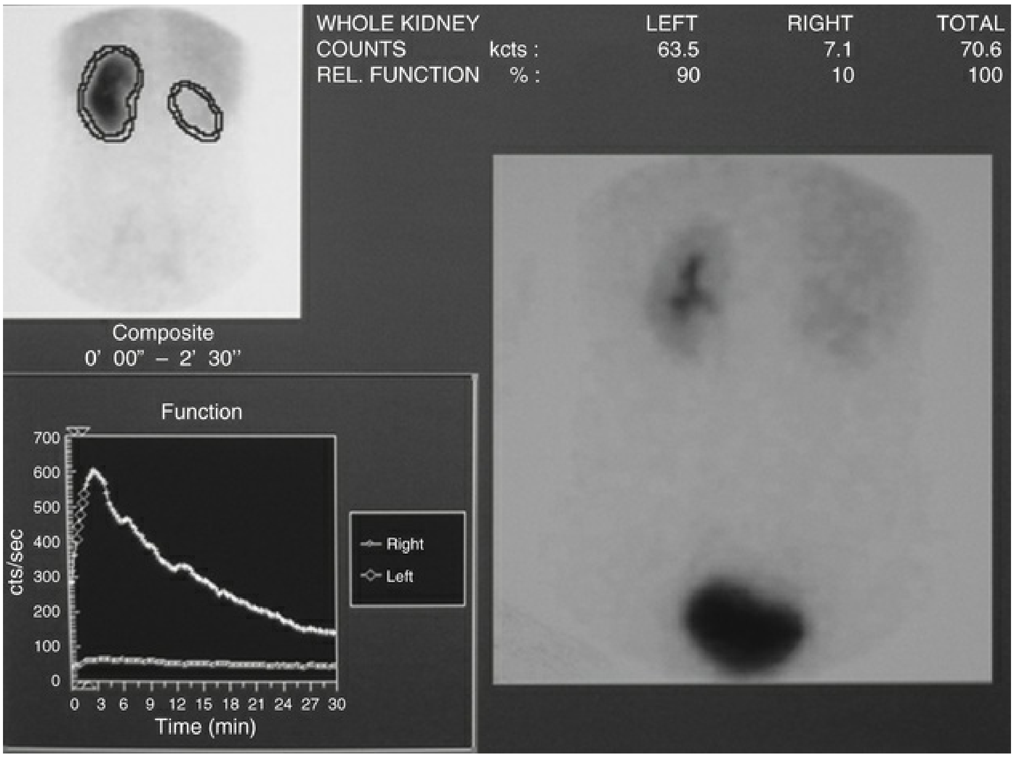

FIG. 121.14 Renal scan of a patient with a grade IV renal laceration and vascular injury.

Renal pedicle injuries are rare and are suggested by a lack of renal contrast enhancement on computed tomography. Renal angiography definitively establishes the diagnosis and directs operative management. Ureteral injuries require operative repair, but diagnosis of ureteropelvic junction disruption may be delayed because of a lack of clinical signs on presentation. Absence of contrast in the ureter indicates that ureteral stent placement will likely be necessary.[35]

Bladder Injuries

Bladder injuries are most often associated with blunt trauma. The bladder is predominantly intraabdominal in children. Therefore burst injuries are more common than in adults. Bladder rupture is associated with pelvic fractures. Clinical presentation of bladder rupture may be subtle, with only mild suprapubic tenderness. The severity of associated injuries may mask signs of a bladder injury. Hematuria is the most consistent finding. Recognizing the injury and identifying it as intraperitoneal or extraperitoneal are important. Stress cystography is best for establishing the diagnosis. Lack of extravasation on computed tomography does not exclude a bladder injury. Peritoneal fluid located in the lateral perivesical recess, superior to the bladder, and in the pouch of Douglas is suggestive of intraperitoneal bladder rupture. Extraperitoneal bladder rupture is noted by fluid extending superior and anterior to the level of the umbilicus and by fluid in the retrorectal presacral space. The distinction between intraperitoneal and extraperitoneal bladder rupture is important for treatment purposes. Controlled extraperitoneal ruptures are treated nonoperatively with urinary catheter drainage. Extensive extraperitoneal rupture and intraperitoneal injuries require operative intervention.[36]

Pelvic Fractures

The most common mechanism resulting in pelvic fracture in children is a pedestrian struck by a motor vehicle. Single fractures of the pelvis are rarely associated with significant abdominal injury, but children with multiple fractures of the pelvis are at significant risk for abdominal injury even if hemodynamically stable (Table 121.3). Pelvic fractures are usually evident on the initial physical examination. Findings include abrasions, bruising, hemorrhage, instability, or swelling. Asymmetry of the bony structure, pain on palpation, or crepitus can be present. An anteroposterior radiograph of the pelvis is obtained in the trauma bay to determine the anatomy of the fracture. After recognition, attention should be directed toward prompt stabilization with a sheet tightly wrapped around the pelvis and assessment of hemodynamic status. Opening of the pelvic ring, associated with fracture at two points, should be stabilized with a sheet wrapped around the pelvis, a C-clamp, or an external fixator. Vertical shear injuries are not usually amenable to this treatment and will require operative reduction. Hemodynamically unstable patients should be aggressively resuscitated. Early angiography and embolization of bleeding vessels help to stabilize patients and avoid the need for operative intervention. Hemodynamically stable patients should undergo computed tomography to evaluate for associated injuries. Special attention should be directed toward the rectum, vagina, and urethra, which are especially susceptible to injury by bony fragments.

TABLE 121.3

Associated Injury by Location of Pelvic Fracture

Fracture Site	Number (%)	Number With Abdominal Injury (%)	Number With Genitourinary Injury (%)
Unifocal	44 (81.5)	5 (11)	0
Pubic ramus	32 (59.3)	2 (6)	0
Iliac/pelvic rim	9 (16.7)	3 (33)	0
Sacrum	3 (5.60	0	0
Multiple	10 (18.5)	6 (60)	4 (40)
Total	54	11 (20)	4 (7.4)

CHAPTER 122

Child Abuse

Paula M. Mazur, Lynn J. Hernan, Sitratullah Maiyegun, Harry Wilson

PEARLS

- Accidental trauma differs from nonaccidental trauma in presentation, workup, treatment, and outcome. In child abuse, the history of trauma is withheld or falsified, and the presenting symptoms are often vague and nonspecific, so the diagnosis and treatment of injuries may be delayed. This contributes to the increased mortality and long-term morbidity seen in abused children.
- Abusive head trauma is the most common nonaccidental injury seen in the pediatric intensive care unit. It is the most common cause of death in abused children. Abusive head trauma is more likely to be fatal and more likely to cause long-term morbidity in survivors than accidental head trauma.
- The infant brain is more vulnerable to injury, especially to shaking (shaken baby syndrome [SBS]). The infant's neck muscles are underdeveloped and the head is proportionately larger than that of the adult. Large cerebrospinal fluid spaces in the infant allow greater movement of the brain within the skull. The infant brain has greater water content and increased deformability. Neurons and axons are less protected because of incomplete myelinization. Increased cerebral vasoreactivity predisposes the infant brain to cerebral edema.
- Accidental head trauma generates translational forces that result in focal damage. Nonaccidental trauma (eg, shaking) generates rotational forces from rapid acceleration/deceleration of the head. Rotational forces tear cerebral bridging veins (creating subdural hematoma) and axons (creating diffuse axonal injury).
- Signs of SBS include subdural hemorrhage, retinal hemorrhage, and skeletal injury. A small number of cases will have all three signs. The presence of subdural hemorrhage and retinal hemorrhage, alone or in combination, in the appropriate clinical setting, are suggestive of SBS.
- Posterior rib fractures, metaphyseal fractures, and spinous process fractures are highly specific for abuse because their proposed mechanisms of injury are unlikely to occur accidentally.
- Abdominal trauma is the second leading cause of fatal child abuse, with death rates approaching 40% to 50%. Inflicted abdominal injury is often occult, presenting without obvious signs or symptoms; thus recognition is delayed. Treatment may be delayed because of a delay in seeking medical attention or a

failure to consider nonaccidental injury in the differential diagnosis.

- Two types of forces are generated in inflicted abdominal trauma. Compression forces crush viscera against the anterior spine, and this crush causes burst injuries of the solid viscera and perforation of air-filled viscera. Deceleration forces cause shear injuries at the site of fixed, ligament attachments. As a result, tears and hematoma formation are seen at the ligament attachments of the liver and small bowel. Children with inflicted abdominal injury often have concomitant injuries suggestive of child abuse (bruises, head trauma, long-bone and skull fractures).
- Abusive thermal burns are of uniform thickness and closely replicate the shape of the inflicting object. Accidental thermal burns have varying degrees of thickness and irregular shapes. Abusive scald burns have an immersion pattern with a burn that is circumferential and is of uniform depth with a well-defined edge, and they spare body creases. Accidental scald burns have more random patterns, vary in depth, have poorly defined edges, and do not spare body creases.
- All cases of suspected child abuse must be reported to child protective services and law enforcement. All cases of fatal child abuse must be referred to the medical examiner. Detailed, legible medical documentation and good communication between the treating physician and the medical examiner are essential to secure the evidence needed to prosecute the case successfully.

Only a small percentage of physically abused children require hospitalization in the pediatric intensive care unit (PICU), but these children have been shown to have a higher morbidity and mortality rate than critically injured victims of accidental trauma.[1,2] The types of injuries that result from nonaccidental injury, coupled with delays in diagnosis and management, account for the worse outcome in abuse victims. Diagnosis and management of life-threatening injuries are often delayed because the history of preceding trauma is not provided or it is so vague or the trauma is depicted as so minor that the physician is led away from a possible traumatic cause for the patient's condition. The so-called golden hour allotted for successful trauma resuscitation is spent considering an infectious, neurologic, or metabolic cause for the child's illness. In addition, there can be a considerable delay in seeking medical care. Several hours to days may elapse between the time of injury and presentation to a medical facility.

Head trauma is the most common type of inflicted injury seen in the PICU, followed by abdominal trauma, burns, and thoracic trauma. Child abuse victims should be approached in the same manner as accidental trauma patients. They may have occult multiple-organ injury. The discovery of one injury demands a thorough evaluation for additional trauma. A meticulous investigation for injury has obvious medical utility, but it also becomes an essential part of the forensic investigation that ensues once a report of suspected child abuse is filed with child protective services and law enforcement.

Recognition of Child Abuse

History of Injury

The history of an injury must account for the type and severity of injury that are seen on physical examination. Suspicion of abuse should arise when any of the following occur:

1. The caretaker is unable to explain the injuries or gives a mechanism of injury that does not match the degree of injury seen. For example, a minor fall would not explain the presence of life-threatening cerebral edema.

2. The timing of the injury does not fit with the time of presentation (eg, a critical head injury cannot be attributed to a fall that occurred 1 week before presentation).

3. The child's developmental stage does not fit the history (eg, rolling off a changing table should raise suspicion if the child is younger than 4 months).

4. The history of injury changes over time or from caretaker to caretaker. A careful review of all histories documented in the medical record may reveal discrepancies.

Patterns of Injury

Inflicted injury may be differentiated from accidental injury by its appearance, location, and distribution on the body (Table 122.1).

TABLE 122.1

Patterns of Injury

Accidental	Nonaccidental
Unilateral	Bilateral/symmetrical
Isolated injury	Multiple injuries
Amorphous shape	Well-defined shape
Prominent bone areas	Soft tissue areas
Posterior aspect of body	Anterior aspect of body
One age of injury	Multiple ages of injury

Bruising

Inflicted bruises are often bilateral, widely distributed, and located on soft tissue areas of the body that are unlikely to make surface contact during a fall. They may take the shape of the inflicting object (eg, fingers, a hand print, linear whip marks from a belt, loop marks from a folded belt or cord). They are frequently found on the posterior trunk, buttocks, and the posterior side of the extremities because the victim would naturally be trying to run away from the perpetrator. Bruise color is not a reliable indicator of the time an injury occurred. Bruises resolve and therefore change color at different rates depending on their location and the force with which they were inflicted.[1] Nevertheless, documenting bruise color is important, particularly with the presence of bruises of markedly different colors at the same time, suggesting that the child may have been abused on more than one occasion. A simple gingerbread-man drawing of the child's body, marked with the locations of all the child's injuries, is a concise descriptive tool that will quickly jar a physician's memory before any legal proceeding.

Early photographic documentation of the child's injuries is essential. The standard for documentation had been 35-mm photographs, but digital cameras, both still and video, are replacing 35-mm photography. Polaroid photographs have been used in court, but they are inferior to 35-mm and digital photographs in both clarity and durability. Every effort should be made to obtain the best photographs; 35-mm photographs/digital photographs taken by a medical or law enforcement photographer are ideal. If a professional photographer is unavailable, any staff member familiar with the use of the camera should take photographs for the medical record.

Burns

Compared with accidental burns, abuse burns are more extensive in degree and distribution, and they often require management in a PICU.[2,3] Inflicted burns are of two types. Thermal injuries involve forced contact with a hot object, and scald injuries involve contact with a hot liquid, usually water. Abusive thermal burns are of uniform thickness and closely replicate the shape of the inflicting object. For example, an inflicted cigarette burn is approximately 8 mm round and uniform in depth. Accidental thermal burns have varying degrees of thickness and irregular shapes. If a child accidentally brushes against a hot cigarette, the burn will be more linear and of varying depth along its length.[1]

Abusive scald burns have an immersion pattern. Part of the child's body, usually the buttocks or limbs, are forcefully immersed and held in hot water. The resulting burn is circumferential and of uniform depth with a well-defined edge called a *tidemark*. Body creases are spared (withdrawal sign) during inflicted scald injury because the child pulls and folds his or her arms and legs inward to avoid immersion in the hot water. Accidental scald burns have more random patterns, vary in depth, have poorly defined edges, and do not spare body creases.[2] Ideally, photographic documentation should be performed before the initial burn dressing. Additional photographs taken 24 to 48 hours later, when the burn has fully evolved in depth and distribution, can also be valuable during litigation.

Fractures

Many of the characteristics used to recognize inflicted bruises and burns can be applied to fractures. The mechanism of injury described by the caretaker must remain consistent, be compatible with the child's developmental stage, and account for enough force to break the child's bone. Inflicted fractures can be bilateral fractures of the same age or multiple fractures in different stages of healing. In his textbook *Diagnostic Imaging of Child Abuse*, Kleinman[4] divides fractures according to their degree of specificity for inflicted injury. Posterior rib fractures, metaphyseal fractures, and spinous process fractures are highly specific for abuse because their proposed mechanisms of injury are unlikely to occur accidentally. Scapula and sternum fractures are highly specific for abuse if the caretaker's history does not account for a tremendous amount of force having been applied to these bones. Fractures of low specificity for abuse are commonly seen after bumps and falls (eg, clavicle fractures, linear skull fractures, long-bone fractures in ambulatory toddlers). Between high and low specificity for abusive trauma are acute, bilateral fractures, multiple fractures of different ages, widened (diastatic) or depressed skull fractures,

and long-bone shaft fractures occurring in the young, nonambulatory infant.

It was long held that spiral fractures were highly suggestive of abuse because their spiral configuration implied that a forceful twisting motion had been applied along the length of the bone. Dalton and colleagues[5] looked at femur fractures in children younger than 3 years, dividing the fractures into three types (oblique, transverse, and spiral), and into three age categories (0 to 1 year, 1 to 2 years, and 2 to 3 years). Their results showed that the incidence of spiral fractures increased significantly with increasing age, whereas the incidence of abuse was highest in the youngest age group regardless of fracture type. Spiral fractures can occur accidentally in vigorous, ambulatory toddlers. The age of the child holds more significance than fracture type when the possibility of inflicted injury is considered.[5,6]

Posterior rib fractures and metaphyseal fractures are frequently seen in shaken or battered infants. Posterior rib fractures occur when the child's chest is compressed. This compression causes the rib to rock back over its articulation with the transverse vertebral process. The transverse process acts as a fulcrum for the rib, and a fracture occurs on the rib's pleural surface. Although this fracture has been seen in pediatric patients with major, high-speed trauma, it does not occur accidentally in healthy children during mild to moderate thoracic trauma. Cardiopulmonary resuscitation (CPR) has not been shown to cause posterior rib fractures. A detailed discussion of posterior rib fractures can be found in Kleinman's textbook, *Diagnostic Imaging of Child Abuse.*[4] Acute rib fractures are difficult to see on a plain film. They may only first be visible 2 to 3 weeks after injury, when a callus has formed around the fracture site. Therefore, finding a callused fracture indicates that the trauma occurred at least 2 to 3 weeks before the radiograph.[4]

The periosteum of a pediatric long bone is loosely attached to its cortex. Any violent pull, tear, or twist on the shaft of a child's long bone displaces the periosteum. This results in subperiosteal hemorrhage and periosteal elevation that can be seen on the radiograph. Conversely, the periosteum is tightly attached at its point of origin, the metaphyseal plate. The metaphyseal plate, which is the most newly laid down bone above the growth plate, has delicate trabeculations. Violent forces applied to the midshaft periosteum are transferred to its point of origin, the metaphyseal plate, and an avulsion fracture occurs through the delicate trabeculae. Depending on the angle at which the radiograph is taken, a metaphyseal avulsion fracture can appear as a thin line through the metaphysis, as “corners” broken off the edges of the long bone or as a “bucket handle” attached to the end of the long bone. Like posterior rib fractures, metaphyseal fractures are pathognomonic for child abuse. These corner fractures or bucket handle fractures are occult. There is no deformity or swelling, and they are not obviously tender to palpation. Like posterior rib fractures, metaphyseal fractures are usually found on a radiograph obtained for other reasons or on a skeletal survey done during the medical investigation of a suspected abuse case. Spinous process fractures are the remaining type of fractures listed under “high specificity” in Kleinman's text. They are thought to occur during infant shaking, when the spine is in hyperflexion, causing sudden stress on the posterior spinous ligament as it articulates with the posterior spinous processes.[4]

Skull fractures are the second most common fracture seen in abused children, but skull fractures are also commonly seen in accidental head trauma. A skull fracture is suspicious for abuse when there is no significant trauma to account for the fracture. An unexplained skull fracture obligates the physician to look for additional injuries

that are pathognomonic for abuse. For example, a skeletal survey may reveal occult posterior rib or metaphyseal fractures. A noncontrast computed tomographic (CT) scan may reveal bilateral subdural hematomas, which are not commonly associated with accidental skull fractures.

The guidelines for dating fractures are broad. In general, periosteal elevation can occur acutely, within hours to days after injury. Callus formation is seen approximately 2 weeks after injury. Loss of the fracture line begins to occur 3 weeks after the injury, and remodeling of the fracture occurs anywhere from 3 months to a year after injury, depending on the child's age. Infants will heal and remodel faster than older children. Skull fractures and metaphyseal fractures are difficult to date because they do not show the same periosteal reactions that healing ribs and long bones do.[4] However, a diastatic skull fracture, which is a linear skull fracture greater than 3 mm wide, is not an acute injury. It takes time for a skull fracture to separate more than 3 mm.

Skeletal Survey

Finding one suggestive injury on a child necessitates a radiologic evaluation of the entire skeleton. Skeletal survey is the most common screening tool used in child abuse investigation. Two views of every bone in the body, radiographed with orthopedic technique, is the gold standard. *Body grams* or *baby grams,* in which the infant's entire skeleton is pictured on one x-ray plate, are unacceptable. It is feasible to obtain adequate surveys at the bedside when the patient has been too unstable to move from the critical care area to the radiology department. It is also possible to obtain postmortem skeletal surveys before transferring the child's body to the medical examiner (ME), because the quality of the surveys often surpasses radiographs performed in the morgue and therefore may serve to focus the ME on particular areas of the skeleton during autopsy.

In general, skeletal surveys have the highest yield in children younger than 2 years of age and are obtained in children up to age 5 years, after which the yield becomes low.[1] Because smaller children are easier to lift, shake, throw, or pull, it is possible to generate the forces required to create the classic abuse fractures previously discussed. Because fractures pathognomonic for abuse, such as posterior rib fractures or metaphyseal fractures, are difficult to see on initial radiographs, it is strongly recommended that a second skeletal survey be obtained approximately 2 weeks after the initial survey. The later survey may reveal callus formation of healing fractures that were not visible on the initial skeletal survey.

Occult fractures can be detected by bone scan, but bone scan is not specific for fracture. The radioactive isotope used in bone scan will also enhance areas of infection, neoplasm, and growth. Therefore positive bone scans cannot be used as evidence of injury in court. A positive scan focuses attention on a particular area of the skeleton in need of closer study, but the area of injury must always be verified by subsequent plain film. Bone scans are most useful in detecting occult rib fractures. They are not as useful in verifying metaphyseal fractures because the metaphysis lies next to an area of vigorous bone growth, and growth areas are normally enhanced in pediatric scans.[4]

Abusive Head Trauma

Abusive head trauma (AHT) is the most common form of child abuse seen in the PICU and is the number one cause of death in child abuse victims overall. Roughly 50% of trauma in children younger than 1 year of age is head trauma. The median age of abusive head trauma victims is 2 to 4 months of age. When Bruce and Zimmerman[7] looked at a population of children younger than 2 years with head trauma, they found that 90% of the head injuries were accidental and 10% were attributed to abuse. Eighty percent of the deaths from head trauma, however, occurred in the smaller percentage of abused children. Outcome studies comparing children surviving accidental and nonaccidental head trauma show significantly higher morbidity rates in the nonaccidental victims. Clearly, abusive head injury differs vastly from accidental head injury.

Characteristics of the Infant Brain and Cervical Spine

The infant brain is more vulnerable to injury than the adult brain for several reasons. The neck muscles inadequately support the infant's head, which is relatively large compared with the rest of the body. Consequently, the head is put through a broader range of random motions during a traumatic event like shaking. The cerebrospinal fluid (CSF) spaces are larger. These spaces allow greater movement of the brain within the skull, and the brain has greater water content, thereby increasing deformability. Open sutures increase skull flexibility so that an infant's skull can be pushed inward causing cortical damage without fracturing. Incomplete myelinization leaves neurons and their axons less protected, and increased cerebral vasoreactivity at the site of injured neurons predisposes the brain to cerebral edema.[8,9] An infant's upper cervical spinal cord is predisposed to injury because of the increased ligament elasticity, poorly supportive paraspinal muscles, incompletely ossified vertebrae with flattened, horizontal facet joints, and increased cord mobility within the cervical canal. In addition, the large infant head causes traction injury to the upper cervical cord during acceleration/deceleration. These factors combined require that the infant with suspected AHT be immobilized in a cervical collar until the cervical spine can be thoroughly evaluated for injury.

Mechanisms of Head Injury

Accidental head trauma, such as a fall from a height, generates translational forces, which are applied directly to the site of impact resulting in focal damage to the cerebral cortex. We may see a focal contusion, a *coup-contre-coup* injury, or an epidural hematoma. Nonaccidental trauma (eg, shaking) generates rotational force as a consequence of rapid acceleration/deceleration movements of the head. Rotational force distorts both gross and microscopic cortical structures.[10] The tearing of cerebral bridging veins creates a subdural hematoma. Axons that are torn at the microscopic level result in neuron death and global cerebral injury.[11] Although subdural hematomas are a hallmark of shaken baby syndrome (SBS), they are rarely life-threatening lesions. The increased morbidity and mortality associated with AHT is attributed to brain injury at the cellular level. This cellular injury has been called diffuse axonal injury (DAI) or traumatic axonal injury (TAI). Increased

vasoreactivity at the site of damaged axons causes a rapid onset of diffuse cerebral edema, which increases intracranial pressure (ICP) and compromises blood flow to vital areas of the brain. Therefore, the child is placed at risk for seizures, respiratory compromise, herniation, and death. Within hours of a shaking injury, a CT scan will begin to show a "black brain" with diffuse edema and a loss of gray-white matter differentiation.[8]

Neuroimaging of Abusive Head Trauma

CT imaging is the universally accepted screening tool for suspected AHT. It is readily available, does not require sedation, and easily identifies subdural hemorrhage. CT scan does not reliably date a central nervous system (CNS) bleed. An acute subdural hematoma may contain both clotted and unclotted blood, each of which has different attenuation on CT. This falsely gives the impression that an acute bleed has occurred within a preexisting or chronic hemorrhage. Magnetic resonance imaging (MRI), although it may require sedation or general anesthesia, is a better tool for identifying subarachnoid hemorrhage, petechial hemorrhage, infarction, hypoxic-ischemic encephalopathy, and axonal injury. Subtle evidence of AHT and its secondary brain injury is more easily seen on MRI. In addition, MRI is a more useful forensic tool than CT imaging during a child abuse investigation. Hemoglobin degradation within a CNS bleed occurs in a predictable sequence and can be roughly timed. Each hemoglobin degradation product has a unique appearance on T1- and T2-weighted images, and an experienced neuroradiologist may be able to narrow down the time of CNS injury. MRI should ultimately be used in all forensic child abuse investigations. Only an experienced neuroradiologist should interpret forensic MRI findings. Ultrasound is not a useful screening tool for AHT.[12]

Retinal Hemorrhages

It is widely hypothesized that the eye is subjected to the same acceleration/deceleration forces that the brain endures. Retinal vessels, coursing through the 11 layers of the retina, will randomly tear, forming hemorrhages of multiple shapes (eg, dots, blots, flame hemorrhages). Hemorrhage shape is determined by the cell orientation in the particular retinal layer where tearing occurs. Intraretinal hemorrhages of multiple shapes in various retinal layers are a classic finding in shaken baby syndrome.[13] Controversy still surrounds the mechanism of retinal hemorrhage formation, and there have been scattered reports of scant retinal hemorrhages found after CPR, in the face of increased ICP (Terson syndrome) or increased thoracic pressure (Purtscher retinopathy). These retinal hemorrhages, however, differ in appearance from the classic retinal hemorrhages of SBS.[13,14] Approximately 30% of healthy neonates will have retinal hemorrhages at birth, but these rapidly resolve by the third or fourth week of life. The retinal hemorrhages of SBS extend into the periphery of the retina, which can only be fully viewed by indirect ophthalmoscopy. The standard for investigation of SBS requires an indirect ophthalmoscopy evaluation by an ophthalmologist and photographic documentation of the retinal hemorrhages using a retinal camera.

Shaken Baby Syndrome

The diagnosis of SBS is made in the presence of a constellation of signs (ie, subdural hemorrhage, retinal hemorrhage, skeletal injury). The mechanisms of injury proposed to cause subdural hematoma and retinal hemorrhage have been discussed. Posterior rib fractures occur when the infant's chest is compressed during shaking. Metaphyseal fractures are thought to occur as the legs and arms are flailed back and forth. Only a small percentage of cases will have all three signs of SBS (subdural hematomas, retinal hemorrhages, and skeletal injury). More than half the cases will show both subdural hematoma and retinal hemorrhage, but the presence of subdural hemorrhage or retinal hemorrhage alone still suggests the diagnosis of SBS.[15]

A proposed sequence of events in SBS would be as follows: The frustrated caretaker impulsively attempts to stop the infant's crying by violently shaking the infant. The infant immediately loses consciousness and becomes apneic, at which time the caretaker impacts the infant down onto the mattress or floor and leaves the child to recover on its own. The cerebral damage and ensuing edema lead to increased ICP, ischemia, seizures, and further respiratory compromise.[1] Eventually medical care is sought for the child. The clinical history is vague, although there is usually some history of altered mental status. The child has nonspecific symptoms such as lethargy, poor feeding, and irritability or may have had a seizure-like episode. The differential diagnosis includes sepsis, meningitis, new-onset seizure, or a metabolic disorder. These children commonly have no external evidence of trauma. Trauma may only become part of the differential diagnosis when CT imaging performed for other purposes reveals intracranial hemorrhage or when a bloody spinal tap fails to clear. Bloody taps that fail to clear should be spun down within 2 hours to look for xanthochromic CSF, which indicates a preexisting intracranial hemorrhage. CSF that has a clear supernatant suggests the presence of blood for less than 2 hours, supporting a diagnosis of bloody tap. For early diagnosis and management of a potentially lethal injury to be facilitated, trauma must always be included in the differential when a young child is seen with altered mental status, seizures, or apnea. Jenny and colleagues[16] reviewed 174 children with abusive head injury who were seen at the Denver Children's Hospital over a 5-year period and found that in 31% of these children, the diagnosis of abusive head trauma was missed on first presentation for medical evaluation. The most frequent misdiagnoses made were gastroenteritis, followed by accidental head injury, sepsis, increasing head size, otitis media, and seizure disorder. Examiners were most likely to make the correct diagnosis if one of the following was present: severe respiratory symptoms, seizures, facial or scalp injuries, or single-parent household. Cases were often missed in the youngest patients, white infants, infants with less severe symptoms, and two-parent households.[16]

Inflicted Abdominal and Thoracic Trauma

Abdominal Trauma

After head injury, abdominal trauma is the second leading cause of fatal child abuse. Death rates approach 40% to 50%.[17] Cooper and associates[10] reviewed 10,000

pediatric patients with trauma who were admitted between 1972 and 1986, identifying approximately 4400 victims of inflicted injury. Of these, only 22, or 0.5%, had abdominal trauma, but the death rate for this small subgroup was 45%. Several factors probably contribute to these high death rates. Inflicted abdominal injury is often occult, presenting without obvious signs or symptoms; this delays recognition. There is usually a delay between time of inflicted injury and time of presentation to a medical facility. Parents may not bring the child to medical attention until the secondary effects of severe abdominal trauma, namely, hemorrhagic shock and peritonitis, manifest. Health care personnel further delay treatment by failing to consider nonaccidental injury in the differential diagnosis. In the study by Cooper and associates,[10] the mean time of delay between injury and presentation for medical care was 13 hours. Of significance, all of the children with inflicted abdominal injury in the study by Cooper and associates[10] had concomitant injuries commonly seen in child abuse. Ninety-five percent had soft tissue injuries, 45% had head trauma, and 27% and 18% had long-bone fractures and skull fractures, respectively. Half of the families had been previously reported to child protective services for suspected abuse or neglect. The most recent abdominal injuries seemed to represent an escalation of abuse in the home. Therefore, any suggestive injury should prompt physicians to look for occult abdominal trauma and to contact child protective services for investigation of the child's social situation.

Children with nonaccidental abdominal trauma tend to be older (>1 year) than children with abusive head trauma. Because they are larger and ambulatory, they are more difficult to grab, lift, and shake, but they are still vulnerable to physical blows. Inflicted abdominal trauma is blunt force applied to the abdominal wall, usually a punch, kick, or blow to the midepigastrium. Two types of force are generated. Compression forces crush viscera against the anterior spine, and deceleration forces cause shear injuries at the site of fixed, ligamentous attachments. We may find burst injuries of the solid viscera, perforation of the hollow, air-filled viscera, or tears and hematoma formation at the ligamentous attachments of the liver and small bowel.[10] The spectrum of inflicted abdominal injuries varies from that seen in accidental abdominal injury because the force of an inflicted blow is concentrated in the midepigastrium. Most inflicted injury will involve the small bowel (duodenal hematoma), liver lacerations, and pancreatic injury. A wider array of injury is seen in accident victims, involving kidneys, spleen, liver, and, to a much lesser extent, small bowel and pancreas.[11,17] Pancreatitis is rare in childhood, and trauma is the primary cause. Unless there is a history of significant injury to the epigastrium, nonaccidental injury must be strongly considered when pancreatitis is found in young children. Given the occult nature of nonaccidental abdominal trauma, CT scan of the abdomen is the evaluation of choice when intraabdominal trauma is being ruled out in child abuse victims.[4]

Child abuse consultants often screen for occult abdominal injury using hepatic transaminases. Lindberg and colleagues[18] conducted a multicentered prospective observational study of children younger than 60 months of age who were referred to a child abuse consultant for a physical abuse evaluation. Of the 1676 patients recruited to the study, 1276 were screened with hepatic transaminases (76%). Fifty-four (3.2%) of the 1276 screened patients were found to have abdominal injury on CT. The authors concluded that 3.2% does not justify routine screening for abdominal injury using CT. Of the 54 patients with verified abdominal injury, 14

(26%) had no clinical signs of abdominal injury and the decision to screen the child with CT was influenced by the child's hepatic transaminases. The authors used a threshold of 80 IU/L for either alanine aminotransferase or aspartate aminotransferase, which is a lower threshold than previous authors have used when studying the same question. Using a threshold of 80 IU/L, the sensitivity and specificity of hepatic transaminases as a screening tool for occult abdominal trauma were 77% and 82%, respectively.[18]

Thoracic Trauma

Beyond the pathognomonic rib fractures of child abuse, extensive thoracic trauma is rarely seen. A child's thoracic cage is so plastic and deformable that even in the absence of rib fractures, a child abuse victim could sustain compromising pulmonary injuries, namely, pneumothoraces, hemothoraces, or pulmonary contusions. As with abdominal trauma, the physician's index of suspicion must remain high to avoid delayed management of a life-threatening thoracic injury. The reader is referred to subsequent chapters of this text for detailed discussions of pediatric thoracic trauma.

Sexual Abuse

Physically abused children may also be sexually abused. When a patient is examined for evidence of physical trauma, a careful genital examination is warranted. Any evidence of old or new genital trauma must be documented with photographs. Genital trauma is usually subtle, difficult to recognize, and difficult to photograph. When possible, consult a physician who specializes in sexual abuse and who may be able to perform a noninvasive colposcopic examination of the external genitalia. The best photo documentation of genital injury is obtained with a colposcope. Of great significance, using colposcopy to videotape and photodocument a child's forensic exam eliminates the need for repeat examinations on the already traumatized sexual assault victim. If acute genital trauma is suspected or identified, a *rape kit* or forensic collection of evidence must be performed, and the police must be involved early in the process. The forensic evidence becomes legal documentation of the sexual assault, and a chain of evidence must be carefully maintained between the hospital and the forensic laboratory. All cultures must be collected in culture medium or broth. DNA probes for gonorrhea and chlamydia cannot be used as evidence in court. Ideally, evidence collection should occur before any washing of the genitalia, including before the skin prep for insertion of a Foley catheter. Speculum and bimanual examination of sexually abused children are not warranted unless there is concern about internal lacerations in need of surgical repair. To avoid the need for repeat examinations, a sexual abuse expert or pediatric gynecologist should perform this examination with the patient under anesthesia.[1]

Protocol for the Medical Investigation of Child Abuse

To ensure complete and objective evidence collection during the medical investigation of child abuse, we have established an investigative protocol for our

institution that is based on the current medical literature. This protocol has worked well across all pediatric subspecialty services in our institution and has provided consistency when communication occurs with law enforcement, legal services, child protective services, and our community pediatricians (Box 122.1).

Box 122.1

Protocol for Medical Investigation of Child Abuse

Physical examination for skin and genital trauma

Photography of all injury

Skeletal survey for children <5 years

Bone scan (if skeletal survey results are negative)

CT head scan for children <3 years

Ophthalmology consultation to rule out retinal hemorrhage

Abdominal trauma laboratory values

Serum amylase/lipase

Liver enzymes

Urine analysis

CT abdomen scan

All nonverbal children

Positive findings from abdominal examination

Abnormal laboratory results

MRI of the head if AHT is identified on CT or is strongly suspected despite equivocal CT findings.

Fatal Child Abuse

Fatal child abuse is not merely a phenomenon of the 21st century. There have been reports of fatal child abuse throughout history. Caligula's daughter died of inflicted head trauma in AD 41. The French literature records the fatal whipping of a 4-year-old girl in the 1850s. In 1860, Professor Ambroise Tardieu published a paper describing fatal physical and sexual abuse inflicted on infants and children by parents. Tardieu's account listed thermal burns, fingernail imprints, contusions due to pinching, intracranial hemorrhages, and other injuries similar to those seen today. Likewise, these parents and caretakers offered explanations for the injuries that were

incompatible with the severity of injury, such as falls during play or by other minor accidents. Knight[19] concluded, in his historical review of child abuse, that fatal child abuse is nothing new.

Eighty percent of fatal child abuse is caused by head injury. Because many of these children undergo surgical intervention before their death, the forensic pathologist/ME is often faced with an autopsy in which the injuries have been altered by surgical procedures. An exact description of the injuries present before treatment is essential: for example, the extent (amount), location, and radiologic information (CT, MRI, plain films) of all epidural, subdural, and subarachnoid hemorrhages. The chart must reference any biopsy specimens (usually blood clots) submitted to the pathology laboratory during surgical procedures. Documenting the extent and location of retinal hemorrhages may assist the forensic pathologist/ME during gross examination of the eyes. Although there are nontraumatic causes of retinal hemorrhage, CPR is not a common cause. The location and size (in inches/centimeters) and a brief description of any abrasions, lacerations, and contusions should be stated. With respect to contusions, the color on admission and on successive days should be recorded. Likewise, any skin breakdown following medical procedures, notably on the posterior scalp and neck, needs documentation.[20]

As previously stated, visceral trauma is the second leading cause of death in child abuse. Abdominal injuries include liver, spleen, intestinal, mesenteric, and renal contusions, lacerations, and rupture. There may be minimal external evidence of such catastrophic injuries. In the event that they are discovered during surgery, the amount of blood in the peritoneum and extent of organ damage should be carefully documented. Abdominal injuries resulting from CPR are extremely rare.[21]

Osseous Injury in Fatal Child Abuse

Fractures of bones in fatal child abuse are evidence. Documentation of the site of fracture (eg, metaphyseal distal femur), type of fracture (eg, transverse, spiral), and possible dating by x-ray analysis should be done on all cases. A head-to-toe approach with skeletal survey will aid the forensic pathologist/ME by locating injuries before the autopsy. During the autopsy, sections of these fractures are taken. Although some authorities consider histologic dating to be accurate, there are wide variations in the chronologic healing of fractures. Only an approximate time frame can be assigned to a fracture.[22] Osseous injuries will also alert the staff to possible nontraumatic causes such as osteogenesis imperfecta.

Scene Investigation in Fatal Child Abuse

The scene is where the infant became unresponsive, became apneic, or sustained injuries that led to hospital admission. It typically belongs to and is secured by law enforcement officers, so the earlier they become involved, the more timely and accurate the scene investigation will be. Emergency medical service (EMS) providers or firefighters are often the first to arrive on the scene. Their narrative description of the immediate circumstances and surroundings is a crucial part of scene investigation. They are encouraged to describe the place and position in which the child was found; the type of bed and bedding the child was found in; the presence of body fluids (blood, vomit, urine, feces) at the scene; the tidiness of the environment;

and the presence of drugs, medications, drug paraphernalia, or alcohol at the scene. They often record the initial reactions of caretakers, identify potential witnesses to the preceding events, and discover other vulnerable children within the household. Talking to EMS providers on their arrival with the critically injured child can provide a wealth of information leading to early suggestions of child abuse/neglect, timely medical interventions, and early law enforcement and child protective services involvement.

Autopsy

The successful identification of tragic fatal child abuse cases depends on a team approach. Box 122.2 lists the minimal information desired by the forensic pathologist/ME before autopsy.[23] Clearly this list is best assembled as a collaborative effort of EMS, law enforcement, and physicians. Ideally, representatives of the pediatric team, law enforcement, and the district attorney's office would attend the autopsy examination. Although law enforcement attendance is routine in all fatal child abuse cases, numerous constraints interfere with pediatric presence at autopsy. Minimally, a phone conversation between the ME and the pediatric attending physician is strongly recommended.

Box 122.2

Scene Investigation Information

Law enforcement jurisdiction

Date, time, address of place of injury

Witnessed by whom (or unwitnessed)

First responders to scene

Field interventions (CPR, intubation, drugs)

Description of victim as found

Description of environment

Scene diagram (supplied by law enforcement)

Interviews with parents, caretakers, witnesses

Cardiopulmonary resuscitation

Organ Procurement Organization and Fatal Child Abuse

The limited supply of organs for transplantation is well known. Although all age groups are represented, there is a lower organ donation percentage in the pediatric age group because this group has a lower relative death rate. Thus the use of organs from the pediatric age group is critical. When a child or infant sustains injuries

leading to brain death, organ procurement is sought by organ procurement organizations (OPOs). Initially, some forensic pathologists/MEs may deny the use of organs on the basis that it may cause problems with judicial procedures.[24] This is not absolute. All three agencies must examine each individual case. The district attorney, forensic pathologist/ME, and the pediatrician must work with the OPO to see if organs not damaged by injury may be used in transplantation. If all parties are satisfied, then a representative of the ME's office (ideally the forensic pathologist/ME who will do the autopsy) should be present when the organs are retrieved for transplantation. The interacting groups are listed in Box 122.3.

Box 122.3

Key Groups Needed for Tissue Procurement

Documentation and Testifying in Court

Testimony of medical personnel begins with thorough and legible documentation in the medical record. Complete, rather than brief, documentation is strongly recommended, because trials may be delayed for months to years. Handwritten notes will become a memory lifeline during testimony. One must document information objectively. Be specific about where information originates. When recording conversations with caretakers, place their exact words in italics and write "per conversation with . . . ." Months to years later, one will not remember exactly who was interviewed or who actually said what is written in the chart. Written words may be misconstrued as opinion, and defense attorneys frequently make this an issue when witnesses testify to confuse or discredit testimony.

Testifying on behalf of a child who has been abused or murdered is emotional. Stick to the facts and remain objective. Remember that medical personnel are not the judge in this case. Stay calm, particularly when being cross-examined by the defense attorney, and remember that medical personnel and their work are not on trial. There is no urgency in court. Take the time you need to formulate answers. Responses should be brief and limited to the questions asked, unless one is specifically told to elaborate further. If a question is not understood, ask that it be clarified before an answer is given. If a detail (eg, a date, a time, a person's name) cannot be recalled, simply state so. One is allowed to refer to the medical records once they have been entered into medical evidence. If a witness does not think that he or she possesses the expertise to answer a question, then the witness should simply state so.

The more prepared one is, the less stressful the experience in court will be. It is the responsibility of medical personnel to review the medical records, laboratory

reports, and radiologic studies before trial. If the prosecuting attorney is properly preparing the case, the attorney will meet with each witness before testimony is given. This meeting gives both the attorney and the witness a chance to clarify specific issues that will be raised in court and to discuss the limits of the testimony. One may be asked to submit an updated curriculum vitae to establish credentials. If one is being called as a fact-finding witness, the court will not solicit opinions. During the trial, one may be qualified as an expert witness in his or her medical subspecialty. Then, one will be allowed to express opinions more freely.

If one is called to testify again regarding the same case or if a deposition was given before trial, then previously recorded statements should be reviewed so that testimony remains consistent. It serves to keep the witness from becoming uncomfortably entangled in unintended contradiction and legal rhetoric when on the stand. Included in the following reference list are suggested readings that may be helpful when preparing for trial.[25-27]

CHAPTER 123

Violence-Associated Injury Among Children

Jesus Peinado, Marie Leiner

PEARLS

- Exposure to violent media, access to firearms and use of drugs and alcohol are associated with increasingly violent behavior.
- Violence can take many different forms. Identification and screening for violent experiences, identification of children at risk, and early intervention in the clinic and emergency departments can be effective in decreasing future violence.
- In the United States, children are more likely than adults to be exposed to violence and crime.
- Children who are exposed to violence experience short-term and long-term physical, mental, and emotional harm.
- Any single form of adverse childhood experience is likely to be accompanied by others. Exposure to violence is recognized as an adverse childhood experience.
- Violence-associated injury among children is neither randomly nor evenly distributed within the population but rather is focused on particular individuals within particular settings, which emphasizes the importance of recognizing that certain children experience higher risks.
- The effects that result from physical injury may be either physical or a combination of physical and psychologic. Physical and psychologic injuries occur in children who are victims, aggressors, or bystanders. It is important to emphasize that psychologic injuries may occur in the absence of physical injuries.
- Psychologic effects of exposure to violence are independent of the child's role as a victim, aggressor, or bystander and might not become apparent for days or even years.
- An episode of violence-associated injury may be one in a series of adverse events. The eventual emotional outcome will reflect the cumulative load.
- Although current practice is symptom reactive, a more comprehensive approach is necessary to prevent the impact of adverse childhood experiences on adolescent and adult health risks, health status, and social functioning.

Physical-Related Injuries in Children

Violence is the intentional use of physical force or power, threatened or actual, against oneself, another person, or a group or community. It results in, or has a high likelihood of resulting in injury, death, psychologic harm, maldevelopment, or deprivation. Violence is a major cause of death and disability of young people. It is a major health problem in children whether their role is perpetrator, victim, or witness.

Children are particularly vulnerable to violence and injury because of developmental issues, including independence and autonomy, curiosity leading to experimentation (eg, alcohol, drugs, sex), peer group pressure, immaturity, impulsivity, feelings of invincibility, narcissism, and the development of self-identity.[1] Physical trauma caused by violence is primarily linked to physical injuries, while psychologic trauma may or may not involve physical injuries. Its effects are almost always detrimental to the child's emotional and psychosocial well-being. In addition to potentially causing injury and death, violence affects communities by increasing the cost of health care, reducing productivity, decreasing property values, and disrupting social services.[2]

The most common circumstances causing injury are arguments (40%), assaults (20%), and crimes other than assaults (4%). Relationships between the patient and others involved in the incident include friends or schoolmates (38%), siblings or other family members (10%), and strangers (9%). These injurious events may occur on the street, at school, or in the home. Most violence-related injuries are minor. Stabs, cuts, and injuries due to a firearm or blunt object have been described in up to 25% of all injuries. Gun violence poses a serious threat to children and youth. The majority of youth who are murdered are killed with a firearm and nearly one-half of youth suicide deaths involve the use of a gun.[3]

In 2010, there were 2711 infant, child, and teen deaths associated with firearms. On average, there are 7 firearm-related fatalities daily and 52 weekly. Most school-associated student homicides involve a firearm and a single victim and offender.[4] In 2011, 5% of high school students carried a gun on school property and 7% were threatened or injured by a weapon (eg, gun, knife, club) on school property.

Victimization and Perpetration

Some populations are especially vulnerable to victimization. There are well-known risk factors that may not directly cause violence but do contribute to it. Evidence shows an increased risk of being victimized in the context of partner violence. Renner and Slack[5] found that childhood physical and sexual abuse predicted intimate partner violence (IPV) victimization later in life. Other data from East Asia and the Pacific Region reported that children who had been sexually abused had a threefold increase in the risk of IPV victimization later in life.[6]

Risk factors for victimization can be classified into different categories:

Individual risk factors (biological and personal)

- Children younger than 4 years of age

- Children with special care needs
- Early aggressive behaviors
- History of victimization
- Developmental problems
- Learning disorders or disabilities
- Low IQ/low level of education
- High stress levels
- Conflict and violence in the family

Family

- Low parental involvement
- Low parental education and income
- Dysfunctional families
- Poor supervision
- Social isolation
- Family disorganization
- Intimate partner violence
- Parental substance abuse or crime

Community and society

- Schools
- Gender
- Societal norms

- Economic/social policies
- Community violence
- Disadvantaged neighborhood

Protective factors include attributes, characteristics, or elements that decrease the likelihood that violence will be perpetrated.

Settings and Forms of Violence

Child Maltreatment

Child maltreatment represents a major public health concern in the United States and abroad. In the United States in 2012, approximately 3.4 million children were referred to child protective service agencies for suspected abuse or neglect; approximately 686,000 children were determined by state and local child protective service agencies to be the victims of maltreatment. In 2012, an estimated 1640 children died from child maltreatment (rate of 2.2 per 100,000 children). Of child maltreatment fatalities in 2012, 70% occurred among children younger than age 3.[7]

School Violence

School violence is youth violence that occurs on school property, on the way to or from school or school-sponsored events, or during a school-sponsored event. A young person can be a victim, a perpetrator, or a witness of school violence.[8] Youth violence includes behaviors such as bullying, pushing, and shoving, which can cause more emotional harm than physical harm. Other forms of violence, such as gang violence and assault (with or without weapons), can lead to serious injury or death.

In 2012, there were approximately 749,200 school-related nonfatal violent victimizations among students 12 to 18 years of age. Approximately 9% of teachers reported that they have been threatened with injury by a student from their school; 5% of school teachers reported that they had been physically attacked by a student from their school.[8,9]

In a 2013 nationally representative survey of youth in grades 9 to 12, 8.1% of students reported being in a physical fight on school property in the 12 months before the survey. It is not surprising that 7.1% of students reported that they did not go to school on one or more days in the 30 days before the survey because they felt unsafe at school or on their way to or from school. Of surveyed students 5.2% reported carrying a weapon (gun, knife, or club) on school property on 1 or more days in the 30 days before the survey, and 6.9% of students reported being threatened or injured with a weapon on school property one or more times in the 12 months before the survey. Additionally, 19.6% of surveyed students reported being bullied on school property and 14.8% reported being bullied electronically during the 12 months before the survey.[9]

The rates of victimization were greater for males than for females 12 to 18 years of age and greater for those residing in urban and suburban areas than for those residing in rural areas.[10] During the 2011–12 school year, a higher percentage of public than private teachers reported being threatened with injury (10% vs. 3%) or

being physically attacked (6% vs. 3%) by a student from their school. Injury and violence are highly prevalent in disadvantaged subgroups of the population, and social disadvantages are associated with life circumstances that place an individual at an increased risk to sustain certain types of injuries.

School-based preventive programs, family-based programs, and street outreach programs can lower the rates of violence and aggressive behaviors when implemented early in a child's life. These programs develop skills that include self-awareness and control, problem-solving, and conflict resolution.

Media Violence

Exposure to media violence does not have identical effects to exposure to real-life violence. Though their effects are not identical, most studies of media violence report that watching and playing violent media cause short- and long-term aggressive feelings, thoughts, and behaviors. Evidence suggests that one of the most potent ways to teach aggression to young viewers is to coach the behavior in a moral context.

The average child between 2 and 5 years of age watches 20 to 30 hours of television a week and spends 9 to 10 hours per week playing videos games. Both exposures are increasingly filled with scenes of violence, not only on commercial television but also on news outlets. In the media, violence is a quick and effective ending for disagreements and ignores the importance of patience, negotiation, and compromise in resolving conflicts and disagreements.[3]

The General Aggression Model explains the development of conditions, attitudes, and behaviors, including how exposure to media violence contributes to the enhancement of mitigation of these aggressive behaviors.[11] In the short term, the General Aggression Model predicts that violent media exposure can affect arousal, aggressive thoughts, and aggressive feelings, which in turn can influence aggressive behaviors.

Regarding long-term exposure to violent content, evidence suggests that repeated episodes of viewing media violence may result in the development, overlearning, and reinforcement of aggression-related knowledge structures, with the belief that aggressive solutions are both effective and appropriate.[12-14] Exposure to violent media is considered to promote a higher tolerance for violence,[15] moral disengagement and lack of empathy,[16] hypothetical delinquency, and attention deficit disorder in youth.[17,18]

While relational and verbal aggression are more socially acceptable (and carry a lower risk of punishment for the individual), these forms of aggression are more likely to be expressed after exposure to media violence.

Health care professionals should counsel and advise families to have more control over access to violent media and encourage them to reduce exposure to violent media content. Parents should be aware of all the risks associated with violent media exposure to assist their children appropriately according to their developmental level, making sure that violent actions are not learned.

Bullying

Bullying is one type of youth violence that affects and threatens children's well-being. It has been estimated that more than 2 million youth in the United States are

involved in bullying as bullies, victims, or both, and the prevalence of bullying among American teens and preteens is approximately 30%. With the alarming increase in school violence, specifically acts of aggression, it is important to inquire about all possibilities related to aggressive behaviors that may implicate bullying.[19]

Bullying is a public health problem that involves physical, verbal, and psychologic forms of aggression and has been defined as any repeated negative action or aggression intended to harm or bother someone who is perceived as being less physically or psychologically powerful than the aggressor within the context of an ongoing social interaction.[20]

Various factors have been associated with being a bully, a victim, or both, including age (with bullying being more frequent in younger individuals), a lower socioeconomic status, and a lower parents' educational level.[19,21-23] Poor health status, increased health care needs, mental health status, and physical appearance have been associated with being bullied, as have loneliness, lack of social interactions, poor social adjustment, poor academic achievement, and sexual orientation. No substantial differences according to gender have been observed in terms of the frequency of being bullied.[24-30] Youth involved in bullying often experience higher levels of health and academic problems, and they have worse emotional and psychologic adjustment than uninvolved youth.

Those involved in bullying may also experience health problems (psychologic, behavioral, and substance abuse), academic difficulties, and safety and violence issues. Bullying affects youth from all ethnic, cultural, socioeconomic, and gender groups. Carrying weapons has been associated with both being a bully and being a victim of bullying.

Primary care providers must be aware of the potential psychosocial problems that bully, victims, and bully-victims may experience as a result of bullying and be knowledgeable about the interventions available; these include using a multidisciplinary approach involving the parents and children, as well as the school system, and providing appropriate and timely referrals when needed to assist children involved in bullying.[31]

School-based interventions have been shown to be effective in reducing bullying. Other potentially effective components of school-based programs include a well-enforced school antibullying policy, increased student supervision, and parental involvement.

The invaluable contributions of David Finkelhor and colleagues[7,32-34] to the longitudinal study of specific trends in youth exposure to violence, crime, and abuse in the United States have demonstrated a steady decline over the past decade. These results seem to reflect actual reductions, as well as measures not considered that may contain a more contemporary spectrum and scope of violence-associated injury among children. It is clear that environmental changes within their communities expose today's youth to new forms of violence.[35] Thus there is a need to understand and improve the measurements of existing trends, as well as create new measurements. In particular, although previously established trends of victimization may be in decline, children and adolescents may be exposed to violence in the same or more sophisticated ways. It is possible that this perceived decline has revealed only the tip of the iceberg, allowing us to observe other interrelated factors related to violence injury in children.

Psychologic Injury and Psychosocial and Behavior–Related Effects

An episode of violence-associated injury in a child is usually accompanied by visible and invisible factors that should be considered in the current and future treatment of the child. It is important for the practitioner to examine the factors that influence a child's physical and psychosocial well-being after experiencing a traumatic event, because these factors are often difficult to isolate, define, and quantify. In particular, factors related to psychosocial well-being are often overlooked due to their nonspecific presentation and the clinician's unfamiliarity.

An event might involve a combination of physical and psychologic injuries or physical or psychologic injuries only. For one event in which physical injury is involved, a pediatric patient may play the role of the victim, aggressor, or bystander. However, in another event with the same or different participants, these roles easily can be switched such that the victim plays the role of the aggressor, demonstrating the existence of different but concurrent pathways.[36-38]

The effects resulting from physical injury might include physical only or a combination of physical and psychologic effects. Although physical and psychologic injuries occur in children who are victims, aggressors, and bystanders, it is important to emphasize that psychologic injury might occur in the absence of physical injuries. Children exposed to violence-associated injury might experience short- and/or long-term psychosocial and emotional effects. Short-term effects can include child distress, emotional dysregulation,[39] attention deficit hyperactivity disorder (ADHD),[40] anger, depression, anxiety, posttraumatic stress disorder (PTSD),[41] and conduct disorders. Long-term consequences include internalized and externalized psychologic problems such as revictimization,[15] adult depression,[42] somatic problems, aggression, and PTSD. They also include behavioral problems such as substance abuse[43] and health risk behaviors.[44] All these problems are additionally linked to suicidality,[45] obesity, hypertension, and cardiovascular diseases,[46-48] as well as failure in school, incarceration, poverty, and an unproductive[49] and unhappy life as an adult.

Disproportionate Distribution of Violence-Related Injury Among Children

Effect of Inequalities

Violence-associated injuries among children are neither randomly nor evenly distributed within the population but rather are focused on particular individuals within particular settings, which emphasizes the importance of recognizing that certain children experience higher risks.[50] These children, who occupy marginal or subordinate positions within peer hierarchies, will be more susceptible to violence associated with both physical and psychologic injury.[51]

Inequalities due to poverty and low socioeconomic status particularly increase contact with violent events in the child's daily life, including in their house, neighborhood, and/or school.[52] The parents of these children are likely to experience severe stress and depression, both of which are linked to poor social and emotional outcomes for their children. In addition to a lack of financial resources, these parents

cannot provide their children with the human and social experiences that are essential for children to thrive and grow into healthy, productive adults. Mental health services, including detection, referral, and treatment, are often described as inadequate in those confronted by inequalities. Several communication barriers such as culture, linguistic elements, and literacy levels contribute to these disparities.[53-55]

Interconnections Between Injury, Adversity, Exposure to Violence, and Victimization and Revictimization

A practitioner that is in contact with a child who has confronted an episode of violence injury must consider that (1) this adverse episode might occur again; (2) it might not be the only adversity confronted by the child; and (3) its effects will resonate beyond the end of the consultation. Because any single form of adverse childhood experience is more likely to be related to other adverse experiences,[15,56] this co-occurrence is important to consider when identifying and treating children who have been exposed to any type of violence-related injury.[57,58] Focusing on only the current event of violence exposure may substantially underestimate the burden of exposure and fail to adequately capture the impact of possible psychologic injury.[59,60]

Effect of Adverse Childhood Experiences

An episode of violence-associated injury in a child may be just one in a series of adverse events. The emotional outcome will always reflect the cumulative load. Although the current practice is symptom reactive, a more comprehensive approach is necessary to prevent the invariable matching of adverse childhood experiences against adult and adolescent health risks, health status, and social functioning.[61]

The Centers for Disease Control–Kaiser Adverse Childhood Experiences (ACE) study is considered to be a groundbreaking public health investigation into the short- and long-term effects of childhood trauma. This study, which is the largest of its kind to be conducted, evaluated more than 17,000 study participants to assess childhood exposure to multiple types of adversity. The initial ACE study found that two-thirds of the participants reported at least one adverse childhood experience. Of those, 87% reported at least one other adverse childhood experience, 70% reported 2 or more, and more than 20% reported 3 or more. The findings of this study demonstrate the harmful, immediate, and long-lasting effects that adversity has on child development. The immediate cognitive effects include attention problems, learning disorders, and poor school performance. Children threatened with adversity-related trauma may suffer decades later from chronic disease and mental illness, as well as aggressive and violent behaviors. Behavioral consequences include lower or null social skills, depression, anxiety, and antisocial and violent behavior. The basic findings of the original study have been independently replicated with similar results, which increases the spectrum of adverse experiences considered.[62,63]

Adverse childhood experiences include verbal, physical, or sexual abuse and family dysfunction, as well as poverty. Adverse childhood experiences do not occur independently but instead are intercorrelated such that the combined effects of two or more adverse childhood experiences may be greater than their sum. In addition, adverse childhood experiences make individuals more vulnerable to suffering from

the same or new adverse experiences, which are often triggered by their own actions as a result of disturbances to their development caused by their earlier experiences.[64]

Pervasive Effect of Violence Exposure

Exposure to violence is recognized as an adverse childhood experience and a form of victimization that has been documented in both retrospective and prospective studies as a basic cause of morbidity and mortality in adults.[65-67] Single or intermittent stress responses from this exposure affect child development and profile the future behavior of the child as both a victim and perpetrator. Thus a cycle occurs with outcomes that often interact such that the child turns to one, a few, or all of the following: victim to further victim either at home or the community, victim to child abuser, victim to perpetrator of violence against his or her own partner, or victim to perpetrator in the community as an antisocial offender.[68]

Although adverse experiences confronted by a child have an effect on his or her adult health and behavior, exposure to violence when encountered at any time during the life span from birth to adulthood almost invariably produces more violence. Systematic efforts to assess these connections have found an overlap among different forms of violence; even diverse and unrelated forms of violence are linked to such an extreme that it can be difficult to identify a group of individuals that have sustained or perpetrated only a single form of violence.[69]

Excessive or prolonged activation of stress response systems in a child can have damaging effects on learning, behavior, and health across the life span. Learning to cope with adversity is an important part of child development. Both adults and children confront stressful moments in life with increases in heart rate and blood pressure and the production of stress hormones. Although the physiologic responses of children and adults are similar, the child's inability to use the resources that experience and maturity give to an adult leaves the child more vulnerable. When the child's response to a stressful situation is activated within an environment of supportive relationships with adults, the damaging effects are buffered and brought back to baseline. Under these circumstances, the child develops a healthy stress response system. However, prolonged chronic stress and frequent stress response activation without the presence of buffering relationships can disrupt the development of brain architecture and other organ systems with lifelong consequences. For example, abuse during early childhood/adolescence is associated with a reduced hippocampal volume and subsequent problems with memory and PTSD risk. This adversity has been associated during later adolescence with a diminished frontal cortex volume, which has been implicated in externalizing behavioral problems. Gray matter abnormalities in regions that form affective and inferior frontal cognitive networks suggest a disturbance in the normal development of these networks as a consequence of early adversities and chronic stress, causing cognitive and emotional problems.[70]

Victimization and Revictimization

Adult health is highly impacted by the cumulative burden of victimization with abnormalities that may not manifest until adulthood.[71] Studies have found that women experiencing exposure to gender-based violence between 2 and 10 years of age had more than 18 times the odds of developing a lifetime mood/anxiety disorder

or substance abuse disorder.[58] Exposure of adolescents to community violence was particularly associated with elevated symptoms of anger, and this exposure predicted levels of externalizing problems and trauma symptomatology over and above the effects of child maltreatment.[72]

Revictimization studies indicate that victims of violence are often exposed to multiple types and occurrences of victimization.[73] The process underlying the theoretic approaches that explains this recurrence indicates that victims exposed to violence learn and develop differently from those who have not been exposed.[74] Victimization will predispose youth to a lack of learning of social, copying, and negotiation skills, as well as make wrongful assumptions about the effect of violent tactics that are considered as successful, acceptable, and appropriate. It has also been mentioned that victims who use avoidant strategies to manage emotions will have difficulties with detecting the signals of a dangerous situation, which in turn leads to missing the opportunity to avoid the risks involved.[75] Among young children, revictimization problems often occur within the same family. Sibling victimization tends to include recurrent episodes, with studies reporting a high prevalence and association of similar experiences with peers.[76,77] Victimization by a sibling is predictive of peer victimization for children and adolescents with elevated mental health distress.[78] Recognition of injury episodes involving sibling victimization is more frequent among children than adolescents.

Detecting and Referring Children for Further Treatment

Psychologic effects on children after exposure to violence independent from the child's role as the victim, aggressor, or bystander might not be apparent for a few days, months, or years after the incident. In addition, existing psychologic problems, adversity, and previous victimization can further aggravate the situation. Recognizing that short- to long-term effects depend on previous victimization, age, and the level of adversity to which the child is exposed, as well as any previous psychosocial or behavioral problems, provides a comprehensive spectrum of what to expect and consider for follow-up.

Studies suggest that one in five children and adolescents may have a pediatric mental, emotional, or behavioral disorder that needs to be identified and requires treatment. The crucial role of early intervention services to improve outcomes for children with developmental and mental health problems has a tremendous impact on children's lives, as well as the lives of their families and society as a whole. Child assessment relies heavily on accurate and appropriate screening, which is recommended to occur at every opportunity, including general health care visits, nonemergency visits, and visits to the emergency department.[79,80] Clinical judgment alone is an insensitive means to identify developmental and behavioral problems,[81] particularly among minority or non–English-speaking children and parents.[82]

Assessments that (1) provide a wider psychosocial profile of the child to adolescence, (2) are standardized by gender and age, and (3) are validated in different languages are recommended. However, most of these assessments require staff to score the responses of parents or guardians to interpret the results. Standardized scales to detect psychologic and behavioral problems can provide precise information about the child with certain restrictions. For example, these assessment scales can screen for the risks of a disorder but cannot provide a diagnosis. The results obtained can be confounded by communication disparities

among those responding to the scales. The majority of these communication problems can be attributed to disparities due to lower levels of education, lack of language proficiency, low literacy, and cultural differences.[83,84] The validation of the psychometric properties of these scales in different languages needs to be considered when selecting either a low or broadband scale for screening specific problems. When the child is old enough to respond, it is important to obtain both self-reports and parental reports to better assess the problem.

Several behavioral and emotional screening tools are available in the public domain, as reported by the Committee on Psychosocial Aspects of Child and Family Health, Council on Early Childhood and Society for Developmental and Behavioral Pediatrics.[85] One of the most popular assessment tools available is the Child Behavior Checklist, which provides information about behavioral and emotional disorders.[86] This assessment tool provides a full spectrum of emotional or behavioral problems among children from 18 months to 18 years old with detailed documentation for deciding what action to take with respect to referral to specialists.

Challenges for Follow-Up and Opportunities for a Teachable Moment

It is uncommon to expect youth to open up about psychologic distress during a traumatic episode.[87] In addition, engaging young people and their parents in mental health services is a recognized challenge, especially among those from a lower socioeconomic status or minority backgrounds. Referrals for follow-up might not occur in many cases due to economic, cultural, health literacy, language proficiency, and educational disparities. Therefore, additional counseling is required to inform parents and youth about the benefits of follow-up sessions.

The teachable moment after a medical incident in the emergency department is a technique that motivates individuals to become more receptive to behavioral change interventions following a traumatic event.[88] Most violent victimization acts are preventable.[89] The teachable moment can be used as a parental intervention. It is crucial to engage the parents as important agents of change, as well as partners for treatment goals that include the environment to achieve better functioning and developmental trajectories.[90] Their influence has been shown to have a significant impact on the emotional health of children even when families are subjected to extreme adversity.[91] Although there is no theoretic model that will predict with certainty which individuals will become aggressive, most theories produce acceptable results in predictions of a nonviolent outcome when all negative factors are removed.[92] However, these findings also suggest the existence of factors that mitigate the harmful effects of adversity, inequalities, and exposure to violence above the child's own resilience factors, which need to be considered and nurtured to make a difference in the life of a child. Positive social relationships, including the positive atmosphere of siblings and other family members, can buffer emotional and behavioral disturbance, which can be attained by providing parental education.[93]

SECTION XII

Pharmacology and Toxicology

OUTLINE

CHAPTER 124

Principles of Drug Disposition in the Critically Ill Child

Jeffrey L. Blumer

PEARLS

- Studies devoted to the disposition of drugs in critically ill patients and children are limited.
- Therapeutics is the branch of pharmacology concerned with the use of drugs for their therapeutic effects. It focuses on four fundamental questions that can serve as an outline for the clinician designing any pharmacotherapeutic plan: what drug, what dose, what route, and how long?
- Drug disposition is controlled by pharmacokinetics and pharmacodynamics. Pharmacokinetics is the discipline within clinical pharmacology that broadly describes the changes in the quantity of drug or drug metabolite in various body compartments over time. Whereas pharmacokinetics describes what the body does to the drug, pharmacodynamics encompasses the pharmacologic aspects that impact how the drug affects the body.
- Pharmacokinetic processes that influence drug disposition include absorption, distribution, metabolism, and excretion. Both ontogeny and critical illness may significantly impact any of these processes. Metabolism may be further affected by genetic differences in involved enzymes.
- Ontogeny and critical illness affect pharmacodynamics in infants and children, although formal study of these effects is limited.
- Pharmacotherapeutic strategies that can be used in the critically ill patient include the target concentration and target effect strategies. The target concentration strategy relies on the concentration of drug in blood or plasma (usually) to guide therapy; this approach is best applied to drugs used chronically for signs or symptoms that manifest intermittently. The target effect strategy, the strategy most commonly used in the pediatric intensive care unit, relies on an accepted clinical end point to determine drug dosing; clinical evidence of toxicity also impacts dosing. The latter strategy probably is the most

reliable means by which to administer the right amount of drug to a highly variable patient population.

Pharmacology is the study of the interaction between chemical agents and biological systems. When these chemical agents are used with the intent of palliating or curing disease, the agents are termed *drugs*. Perhaps nowhere is drug therapy more important than in critical care. In this setting, however, drug response often is difficult to predict. Physiologic aberrations and coincident pharmacologic and nonpharmacologic therapies may thwart intended drug effects. For the pediatric intensive care physician, pharmacotherapeutic decisions are further complicated by ontogenetic differences in drug processing and response. Finally, experience upon which to base pharmacotherapeutic expectations or prescription is sparse. Most drugs used in the intensive care setting have never been formally investigated in critically ill patients, let alone in children. As such, it is imperative that the pediatric intensive care physician have an understanding of the pharmacologic and related developmental constructs that influence drug response in patients.

The discipline of therapeutics provides a useful outline by which to design and monitor drug treatment. *Therapeutics* is the branch of pharmacology concerned with the use of drugs for their salubrious effects. It focuses on four fundamental questions pertaining to drug therapy as it relates to patient care: what drug, what dose, what route, and how long? The task of answering these important questions is facilitated by an understanding of the general pharmacologic principles that dictate drug response and the factors that lead to variation among patients.

Drug Disposition in Infants and Children

It should come as no surprise that controversy exists regarding drug dosing in pediatric patients. Over the years, a number of dosing rules been developed with the intent that drugs be safely administered to young children. All these rules depend on the standard adult dose with a scale-down factor based on body weight or age. However, distinct differences in pharmacokinetics and pharmacodynamics (Box 124.1) distinguish the pediatric patient from the adult patient. Critical illness may further alter pharmacokinetics and pharmacodynamics in children. These differences must be recognized before providing safe and effective dosing and during the initial selection of the drug itself.

Receptor/effector coupling

Safety profile

Determinants of Effective Therapy

Effective therapy results when the drug selected for a given condition has both favorable pharmacokinetic and favorable pharmacodynamic properties (see Box 124.1). Moreover, administration to the patient must be individualized based on (1) a realistic clinical end point determined before administration, (2) sound knowledge of the quantitative aspects of the disposition of the drug selected, and (3) an understanding of the impact on the patient's illness of both the dosing regimen to be used and the anticipated therapeutic effect.

Pharmacokinetics

Pharmacokinetics is the discipline within clinical pharmacology that broadly describes the changes in the quantity of drug or drug metabolite in various body compartments over time. These changes can be described by four processes: absorption, distribution, metabolism, and excretion. Each of these processes can be affected by both development and disease. A clear understanding of pharmacokinetic processes and the factors affecting them will permit the clinician to design an effective treatment plan or to troubleshoot when an undesired response to treatment occurs. In other words, an understanding of basic pharmacokinetic principles will increase the likelihood that any treatment goal will be successfully accomplished with minimal adverse effects.

Drug Absorption

Absorption refers to the translocation of a drug from its site of administration into the bloodstream. When drugs are administered intravenously, as often occurs in the intensive care unit (ICU), the need for absorption is bypassed. When intravenous administration is not possible or convenient, several other routes of administration can be effectively used. Physicochemical properties of the drug and specific factors related to each route determine the rate and magnitude of absorption. Knowledge of these factors increases the likelihood that the clinician will be able to predict, if not control, this component of drug disposition.

Absorption of drugs from the gastrointestinal tract is affected by a number of factors (Box 124.2).[1,2] In general, enteral absorption depends on gastric emptying, intestinal surface area and motility, and hepatic first pass. Ontogeny and critical illness may significantly affect these and other patient factors (Fig. 124.1 and Box

124.3).

Box 124.2

Short bowel syndrome

Protein/calorie malnutrition

Bioavailability (F) describes the fraction of a dose of drug that reaches the systemic circulation. Bioavailability of a single drug may vary significantly depending on the route of administration. By routes other than intravenous, absorption is a primary determinant of F. In enteral administration, an additional factor influences F. Excluding drugs primarily absorbed by the oral mucosa, drugs administered into the gastrointestinal tract may undergo metabolism by intestinal mucosal cells or metabolism or biliary excretion when they pass through the liver, before reaching the systemic circulation. This is known as the *first-pass effect*. With affected drugs, this phenomenon may significantly reduce F. This accounts for the fact that the enteral dose for many drugs is significantly greater than the intravenous dose. The susceptibility of a drug to hepatic first-pass metabolism may influence how the drug is administered; for example, nitroglycerin is given sublingually to circumvent a considerable first-pass effect in this drug.[3] Aside from the physicochemical nature of

the drug itself, other factors may influence the extent of hepatic first-pass metabolism. Changes in hepatic blood flow may alter this action.[4] Age likely further influences the extent of hepatic first pass. As described later in the chapter, maturation of hepatic enzyme systems and transporters appears to occur postnatally.[5] Although the data dedicated to the ontogeny of metabolizing enzymes and transporters in the liver are limited, particularly as they relate to drug bioavailability, F probably decreases with age as these systems mature.[5]

Intramuscular Administration

The parenteral route of drug administration is important when a patient's disease state precludes oral therapy or when the bioavailability of an oral formulation is poor. The intravenous route for drug delivery is preferred over intramuscular (IM) injection. However, in children with poor intravenous access, IM injection is a viable and effective alternative for the administration of many drugs. Both physicochemical and physiologic factors affect the rate of drug absorption from the IM injection site.[6] Lipophilicity of a drug favors rapid diffusion into the capillaries; however, the drug must retain a degree of water solubility at physiologic pH to prevent precipitation at the injection site. For example, the sodium salt of phenytoin is principally an acid and thus is insoluble in the extracellular milieu of skeletal muscle. This explains the poor IM absorption of phenytoin. By contrast, phenobarbital and benzathine penicillin are well absorbed after IM administration. Both of these drugs are weak acids with pK_a values close to physiologic pH and are therefore unlikely to precipitate in muscle under most physiologic conditions. By having knowledge of the physicochemical properties of a drug preparation, the clinician can predict, even control to some extent, how the drug is absorbed. Although aqueous preparations undergo rapid absorption, drugs in a solution of oil or other repository vehicles are absorbed at a slower and more continuous rate.[7]

Another important factor that influences absorption of drug from an IM injection site is local blood flow, which may be compromised in patients with poor peripheral perfusion.[8] Rate and extent of absorption from an IM injection site also are influenced by the total surface area of muscle in contact with the injected solution, similar to the dependency of oral absorption on the total available absorptive area in the intestines.[6]

A final consideration in IM absorption is muscle activity, which may affect the rate of absorption and therefore affect the peak serum concentration. Sick, immobile infants and children or those chemically paralyzed may show reduced absorption rates after IM drug administration. Use of this route of administration in the ICU may be limited by actual or induced (anticoagulant therapy[7]) bleeding diatheses in some patients. A list of intramuscularly administered drugs used frequently in the pediatric intensive care unit (PICU) is provided in Box 124.4.

Subcutaneous Absorption

As with absorption of drugs from IM sites, absorption of subcutaneously administered drugs is influenced by local blood flow, as well as by proximal scarring or injury.[4] The pattern of absorption varies similarly to that following IM injection, depending on the physicochemical properties of the preparation. Frequently, drugs given by the subcutaneous route undergo slow and sustained absorption.[7] As such, the rate of absorption can be regulated by the drug formulation. For example, when drugs are administered in solid pellet form, absorption may occur over weeks to months.[7] Absorption can be slowed by the addition of a vasoconstrictor.[7] This route of administration is not appropriate for large volumes or for drugs that are irritating to tissues.

Percutaneous Absorption

Percutaneous absorption is inversely related to the thickness of the stratum corneum

and directly related to skin hydration.[9] The stratum corneum is generally assumed, but not proved, to be thinner in children than in adults. The integument of the full-term neonate possesses intact barrier function.[10] This is not assured in the case of the premature infant.[11] Another important factor dictating percutaneous absorption is the surface area/body weight ratio, which is much larger in the full-term neonate than in an adult. Theoretically, if a newborn receives the same percutaneous dose of a compound as an adult, the systemic availability per kilogram body weight is approximately 2.7 times greater in the neonate.

The percutaneous route of drug administration is taking on greater importance in the ICU setting. Historically, the most commonly used cutaneous preparation for systemic therapy is nitroglycerin.[12] More recently, advances in the technology associated with drug delivery systems have resulted in the common use of clonidine as a percutaneous preparation for treatment of hypertension and narcotic withdrawal. In addition, a number of narcotics exist as cutaneous preparations so that essentially continuous infusions of these drugs can be safely administered outside the ICU.[13] Finally, even drugs such as nitroglycerin ointment are finding potential new uses in the PICU, for example, treatment of the distal ischemia associated with purpuric injuries.

Rectal Absorption

Rectal administration of drugs is of potential therapeutic importance if a patient cannot take an agent orally and intravenous access for drug administration is impracticable. Because of the routes of the respective venous drainage systems, drugs administered into the superior aspect of the rectum are susceptible to hepatic first pass, whereas drugs administered lower into the rectum initially bypass the liver.[14] This may be an advantage for drugs such as lidocaine or propranolol that demonstrate a significant hepatic first-pass effect. The predominant mechanism for drug absorption from the rectum probably is similar to that observed in the upper gastrointestinal tract (ie, passive diffusion). Theoretically, the physicochemical and host factors discussed earlier with respect to oral drug absorption also influence rectal drug absorption. In general, absorption from aqueous or alcoholic solutions is more rapid than from suppositories.

Lipophilic drugs with pK_a between 7 and 8, such as barbiturates and benzodiazepines, seem to be ideally suited for rectal administration because they exist mostly in unionized form and readily cross cell membranes. Rectal use of drugs such as thiopental and diazepam may be effective when intravenous access is a problem and rapid induction of anesthesia is desired or when a child is convulsing. Dulac and associates[15] showed that rectal administration of 0.25 to 0.5 mg/kg of a diazepam solution to children aged 2 weeks to 11 years produced serum concentrations comparable with those observed after intravenous administration. Additionally, peak serum concentrations occurred within minutes of administration. Potentially effective anticonvulsant serum concentrations were maintained for 1 to 3 hours in most of the study patients. Knudsen[16] demonstrated similar results in 20 children aged 1 to 2 years and further ascertained the clinical efficacy of rectal diazepam in preventing recurrent febrile seizures. In a similar fashion, Burckart and colleagues[17] reported rapid and effective sedation after rectal administration of thiopental suspension to 36 infants and children undergoing computed tomographic scanning.

Drug Distribution

Knowledge of drug distribution is important for selecting the appropriate drug and dose to be administered. Distribution of most drugs in the body is influenced by a variety of age-dependent factors, including protein binding, body compartment sizes, hemodynamic factors such as cardiac output and regional blood flow, and membrane permeability.[18,19] Any of these factors also can be altered by disease. This section briefly reviews the pharmacokinetic description of distribution and the effect of ontogeny and critical illness on several factors that determine drug distribution.

The primary pharmacokinetic parameter representative of drug distribution is the volume of distribution (V_d). V_d reflects the apparent space within the body available to contain drug and relates the amount of drug in the body to its concentration in a biological fluid, usually blood or plasma.[7] V_d varies among drugs, based on the drug's extent of protein and tissue binding and its partition coefficient in fat.[7] Additionally, for any given drug, V_d varies among patients because of differences in protein stores or binding and body composition as a result of age or illness. For example, in neonates and infants, a relatively increased extracellular fluid volume, decreased protein binding, and increased brain and liver size all contribute to increased weight-normalized V_d for most drugs.[20] An understanding of the factors influencing V_d is of paramount importance to the clinician caring for critically ill children. V_d relates the administered dose of drug to its plasma or blood concentration, which determines therapeutic effects, both favorable and adverse. Alterations in V_d produce reciprocal changes in drug concentration.[20] Familiarity with the concept of V_d and the ontogenic and other factors influencing its variation will assist the intensive care physician in understanding why a standard drug dose might be inappropriate for a given patient.

Developmental Aspects of Protein Binding

Plasma protein binding of drugs depends on the concentration of binding proteins available, the affinity constant of the drug for the protein(s), the number of available binding sites, and the presence of pathophysiologic conditions or endogenous compounds that may alter drug-protein interaction.[21] The affinity of albumin for acidic drugs increases, as do total plasma protein levels, from birth to early infancy.[22] These values do not reach normal adult levels until age 10 to 12 months. In addition, although plasma albumin may reach adult levels shortly after birth, the neonatal albumin level in blood is directly proportional to gestational age, reflecting placental transport and fetal synthesis.[23] Binding of basic drugs by α_1-acid glycoprotein also is affected.[20,24] Studies in cord blood suggest that decreased levels of α_1-acid glycoprotein cause this decreased binding.[24] Some of the drugs that have exhibited decreased protein binding in the infant include diazepam, furosemide, propranolol, thiopental, phenytoin, and some antibiotics.[20] The comparative binding of some of these drugs in neonates and adults is given in Table 124.1. The impact of decreased binding of many of these drugs on efficacy has not been determined.[20] For drugs that are highly protein bound and subject to therapeutic monitoring (eg, phenytoin), however, any decrease in protein binding may lower the measured total drug concentration.[20] In such cases, monitoring of free drug concentration (if possible) will prove more clinically relevant.

TABLE 124.1

Comparative Protein Binding of Some Representative Drugs

Drug	% BOUND	
	Newborn	Adult
Acetaminophen	37	48
Ampicillin	10	18
Diazepam	84	99
Lidocaine	20	70
Morphine	46	66
Phenobarbital	32	51
Phenytoin	80	90
Propranolol	60	93
Theophylline	36	56

Data from Kurz H, Mauser-Ganshom A, Stickel HH. Differences in the binding of drugs to plasma proteins from newborn and adult man. Eur J Clin Pharmacol. 1977;11:463.

Developmental Aspects of Fluid Compartment Sizes

Alterations in body water compartment sizes affect the volume of distribution of a drug. Age-dependent changes in the various fluid compartments (Table 124.2) were reviewed in detail by Cheek and coworkers[25] and Friis-Hansen.[26] Regardless of age, critical illness and related therapies may alter total body water and other fluid compartment volumes.

TABLE 124.2

Fluid Compartment Size as a Function of Age

Age	Total Body Water[a]	Extracellular Fluid[a]	Intracellular Fluid[a]
Fetus <3 mo	92	65	25
Term gestation	75	35-44	33
4-6 months	60	≈23	37
12 months		26-30	
Puberty	60	≈20	40
Adult	50-60	20	40

[a]As a percentage of body weight.

At 40 weeks of gestation, measurements of extracellular fluid volume have ranged from 350 to 440 mL/kg body weight. Cassady[27] demonstrated that the extracellular fluid volume of newborn infants correlated more closely with body weight than with gestational age. By age 1 year, extracellular fluid volume decreases to approximately 26% to 30% of body weight. After the first year, it decreases slowly and gradually approaches the adult value of 20% body weight by puberty. Intracellular fluid volume increases from 25% of body weight in the young fetus to 33% at birth to approximately 37% of body weight at age 4 months. Except for a sudden increase during early childhood, the intracellular fluid volume remains relatively constant thereafter, approximating 40% of body weight. The clinical relevance of this gradual reduction in the size of extracellular body water compartments with age cannot be overemphasized. To achieve comparable plasma and tissue concentrations of drugs distributing into extracellular fluid, higher doses per kilogram body weight must be given to infants and children than to adults.[28]

Developmental Aspects of Body Composition

The percentage of body weight composed of adipose tissue approximately doubles during the first year of life.[20] Additionally, the liver and brain account for a higher percentage of body weight in the neonate than in the adult.[11,20] All of these factors may lead to significant differences in weight-normalized V_d between infants and adults, depending on the drug. Differences in the amount of adipose tissue may alter clearance of some drugs.

Critical Illness and Drug Distribution

Because of impaired production or increased losses, respectively, conditions such as liver disease and nephrotic syndrome reduce circulating albumin concentrations, resulting in an increase in apparent V_d. Diseases that induce an acute phase reaction (eg, malignancy, myocardial infarction, inflammatory bowel disease) may provoke increased binding of basic drugs because of increased levels of α_1-acid glycoprotein.[7] Additionally, accumulation of extravascular fluid collections (eg, pleural effusions and ascites) results in the development of a reservoir for drugs that are distributed into the total body water.[29]

Drug Clearance

Clearance reflects the removal of drug from the body. Clearance occurs by two processes: biotransformation (ie, metabolism) and excretion. Metabolism occurs primarily in the liver. Excretion is predominately facilitated by the kidney, although excretion also can occur via exhalation, saliva, sweat, or the gastrointestinal tract.[11,7] Redistribution of a drug can contribute to total clearance if the reference compartment is blood or plasma, as is often the case.[4] When reflected in the blood or plasma, clearance quantitatively describes the volume of blood or plasma from which all drug is removed per unit of time.[4,11] Clearance is an important pharmacokinetic parameter to consider when the goal is to maintain a steady-state drug concentration, which correlates with therapeutic efficacy. Once a steady state is achieved, clearance of the drug determines the quantity of drug that must be administered in order to maintain that concentration (ie, drug out = drug in).[4,5] The clinically relevant pharmacokinetic concepts related to clearance are discussed later in this chapter. The ontogeny of systemic clearance mechanisms probably accounts for a significant portion of the difference in pharmacologic response between infants and adults.[5] These developmental factors also produce variability among pediatric patients. Critical illness may have an additional profound impact on clearance mechanisms.

Hepatic xenobiotic metabolism assumes an extremely important role in determining the pharmacokinetic and pharmacodynamic properties of many drugs. Clearance of a drug (Cl) by an individual organ depends on blood flow to the organ (Q) and the organ's extraction ratio (E) and can be described as follows[30]: $Cl = Q \times E$, where E is the ratio of the arteriovenous concentration difference divided by the arterial concentration (extraction) as expressed by $E = (C_a - C_v)/C_a$, where C_a and C_v are the arterial and venous concentrations, respectively. Organ clearance concepts are best described for the liver and kidneys. Hepatic clearance depends on hepatic blood flow, plasma free drug concentration, cellular uptake, hepatic metabolism, and biliary excretion. The hepatic clearance of a drug can be expressed by the following equation:

$$Cl_H = \frac{Q \times f_B \times Cl_{int}}{Q + (f_B \times Cl_{int})}$$

where Cl_H is hepatic clearance, Q is hepatic blood flow, f_B is fraction of free drug, and Cl_{int} is intrinsic clearance, which is a measure of hepatocellular metabolism. Drugs that are primarily cleared by the liver can be classified as flow limited or capacity limited.[31] If a drug displays a high Cl_{int} and E, then doubling the Cl_{int} will have little effect on Cl_H, whereas a change in blood flow will produce a proportional change in Cl_H. In other words, for drugs that are highly extracted (>80%) and metabolized by the liver, Cl_H reflects the amount and rate of drug delivered to the liver.[32] The considerable declines in hepatic blood flow and oxygen delivery that occur immediately following birth do not appear to translate to significantly reduced clearance of flow-limited drug in the newborn compared with the adult.[5] Drugs with high extraction ratios are subjected to the first-pass effect when administered enterally.

Capacity-limited drugs display low extraction ratios (<20%) and a low intrinsic metabolic clearance. Therefore hepatic clearance depends on the degree of hepatic uptake and metabolism of the drug and is independent of hepatic blood flow. Capacity-limited drugs can be further subdivided into binding-sensitive and binding-insensitive drugs. Binding-sensitive drugs, such as clindamycin, have extraction ratios that approach the free drug concentration ($E = f_B$). Therefore factors that increase f_B, such as decreased protein binding, also increase hepatic clearance. In contrast, other drugs may display extraction ratios that are much less than the free drug concentration. In these cases, an increase in f_B does not enhance extraction of the drug, and therefore the hepatic clearance is a function of the intrinsic clearance and is independent of protein binding. These drugs are referred to as binding-insensitive (eg, chloramphenicol).

At every level, from the ontogenetic changes in hepatic blood and portal oxygen tension to the developmental alterations in protein binding and xenobiotic metabolizing enzyme activities, there is the potential for age to affect the processes associated with hepatic clearance. Very little investigative effort has been expended to elucidate these effects; however, some of the important available data are discussed further. For detailed reviews of this data, the reader is referred to articles by Alcorn and McNamara[5] and Leeder and Kearns.[33]

Biotransformation: Phase I Reactions

The biotransformation of endogenous and exogenous substances occurs primarily in the liver, although the adrenal gland, placenta, kidney, gut, and skin also are capable of metabolizing compounds. Once a drug enters the hepatocyte, it may be transformed by one or more enzymatic reactions. These pathways, or phase I reactions, include oxidation, reduction, hydrolysis, and hydroxylation.[34,35] In general, these reactions are responsible for transforming compounds into more polar, less lipid-soluble molecules that are more rapidly eliminated by the kidney, biliary system, or lung. However, parent compounds may be transformed into pharmacologically active intermediates, such as theophylline to caffeine, or into toxic metabolites, as occurs with oxidation of acetaminophen. In addition, pharmacologically inactive parent compounds (prodrugs) may be converted to

active moieties, as occurs with hydrolysis of chloramphenicol succinate to chloramphenicol. The ontogeny of human enzyme systems differs dramatically from most animal species, especially for oxidation and glucuronidation pathways.[36] Therefore extrapolating data for enzyme system maturation from animals to humans is difficult. Of the enzyme systems capable of metabolizing drugs, the hepatic cytochrome P-450 (CYP) mixed-function oxidase system has been studied in greatest detail. It is responsible for most of the phase I reactions catalyzed in the human liver.

Yaffe and colleagues[37] first demonstrated drug-oxidizing enzymes in the human fetal liver. During fetal life, these enzymes are present at 30% to 60% of adult activity in vitro.[38] Following birth, total CYP levels increase, approaching adult range by age 1 year.[5] Activity of all CYP enzymes is generally thought to be considerably lower in children, particularly neonates and infants, than in adults. In truth, the developmental aspects of expression and function vary among CYP enzyme families and isoforms. Although data delineating these variations are limited, particularly for specific families or isoforms, some insight into the ontogeny of select enzymes has been gleaned from immunochemical studies in hepatic microsomes and tissue, pharmacokinetic studies of known enzyme substrates, and studies evaluating the biotransformation of pharmacologic *probes* (eg, carbamazepine in the case of CYP3A4). The ontogeny and the drugs affected by some of the important CYP isoforms are outlined in Table 124.3. A limited discussion of the most clinically relevant isoforms in pediatric patients follows.

TABLE 124.3

Ontogeny of Select Hepatic Enzymes

Enzyme	Representative Substrates	Developmental Evolution
Phase I		
CYP1A2	Acetaminophen, caffeine, theophylline, warfarin	Negligible in fetal liver. Adult levels of activity by approximately age 4 months. Activity exceeds that in adults after age 1 year; gradually declines to adult levels by end of puberty.
CYP2C9	Diazepam, phenytoin, NSAIDs, tolbutamide, S-warfarin	Undetectable to low in fetal liver. Adult levels of activity by age 1-6 months. Activity exceeds that in adults from age 3-10 years; gradually declines to adult levels by conclusion of puberty.
CYP2D6	Numerous, including captopril, codeine, dextromethorphan, haloperidol, metoprolol, propranolol, ondansetron, tricyclics	Undetectable in fetal liver. Expression and activity appear to be stimulated by parturition. Complete maturation may occur by age 1 year, although acquisition of adult activity levels has been reported to occur as late as age 5 years.
CYP3A4	Numerous, including acetaminophen, amiodarone, budesonide, carbamazepine, cyclosporine, erythromycin, lidocaine, nifedipine, tacrolimus, theophylline, verapamil, R-warfarin	Low in fetal liver; replaces CYP3A7 as the predominant isoform following birth. Based on pharmacokinetic and drug disposition studies, activity in children thought to be greater than that in adults. Decline toward adult levels begins at approximately age 4 years. Adult levels reached by end of puberty.
Phase II		
Uridine 5′-diphosphate glucuronyltransferases (UGTs)	Numerous, including acetaminophen, benzodiazepines, bilirubin, chloramphenicol, dextromethorphan, morphine, naloxone, NSAIDs, propofol, thyroxine	Varies by isoform; difficult to characterize individual isoforms because of overlapping substrate specificities. As a group, activity appears to be deficient in the neonate and infant. Variably reported acquisition of adult levels of activity; anywhere from age 2-30 months, depending on the proposed isoforms involved.
N-acetyltransferase-2 (NAT2)	Caffeine, clonazepam, hydralazine, isoniazid, procainamide	Low activity in neonates and infants. Movement toward adult phenotypes (≈50% fast and 50% slow acetylators) after nearly 3 months of age.
Methyltransferase group (MT)	Catecholamines, captopril, serotonin, spironolactone	S-methylation capacity (TPMT) approximately 50% greater in infants than in adults. Limited evaluating maturation

		after this point; one Korean study demonstrated adult level activity by age 7-9 years.
Sulfotransferase group (ST)	Acetaminophen, bile acids, chloramphenicol, cholesterol, dopamine, polyethylene glycols, salicylates	At least some isoforms well developed in the infant; compensates for deficient glucuronidation of certain substrates (eg, acetaminophen).

NSAID, nonsteroidal antiinflammatory drug.

Substrate listings from Leeder JS, Kearns GL. Pharmacokinetics in pediatrics: implications for practice. Pediatr Clin North Am. 1997;44:55. Additional data related to substrates and all remaining data derived from references cited in the text.

CYP1A2.

Cytochrome P-450 1A2, the only CYP1A isoform found in human liver, is involved in the biotransformation of many drugs, including the methylxanthines.[33] Immunohistochemical studies have suggested that this protein is sparse, if present at all, in fetal liver.[39] These studies also demonstrate that levels of CYP1A2 do not appreciably increase until several weeks to months after birth, remaining below adult levels well into childhood. These findings are reflected in studies examining enzyme activity as assessed by biotransformation of theophylline. Nassif and colleagues[40] reported a significant correlation between a decreasing elimination half-life for enterally administered theophylline and increasing age. Decreased elimination was further suggested by a marked difference in dosage requirement, with patients younger than 4 months requiring approximately half the daily dose needed in patients age 8 to 13 months to maintain therapeutic levels. Tateishi and colleagues[41] evaluated biotransformation of intravenous theophylline, quantifying three metabolites (1-methyluric acid [IMU], 3-methylxanthine [3MX], and 1,3-dimethyluric acid [DMU]) in urine. The ratios of metabolites to theophylline in urine increased dramatically from the neonatal period to age 3 years, when they appeared to essentially plateau. However, a greater variation in these ratios was seen among patients older than 3 years. This study also established that the relative production of DMU, a product of reactions catalyzed by other CYP enzymes, including CYP2E1 and CYP3A4, was higher in the youngest patients compared with those older than 3 years. The relative production of the other two metabolites, which result from CYP1A2 activity alone, is similar between the groups. After age 1 year into early childhood, rates of theophylline clearance appear to exceed the rates in adults, prompting the need for an increased dose to maintain therapeutic levels.[33]

CYP2C9.

The CYP2C family comprises a substantial portion (approximately 20%) of CYP enzymes in the adult liver and has comparable importance in the metabolism of drugs.[5] CYP2C9 is the principal isoform in this family. Enzyme protein is undetectable[42] to low[33,39] in fetal liver. In vitro studies in fetal hepatic microsomes suggest comparably low enzyme activity. Demethylation of diazepam, which is mediated by the CPY2C family, occurs at a level less than 5% that in adult microsomes.[42] On the other hand, hydroxylation of tolbutamide, which is catalyzed specifically by CYP2C9, is not at all evident in fetal microsomes.[42] Several studies, both in vitro and in vivo, suggest an increase in enzyme expression and activity within the first month of life. Following sedation with diazepam, levels of desmethyldiazepam in urine are very low at age 1 to 2 days and increase within the first postnatal week.[42] CYP2C9 protein reaches adult levels in hepatic tissue after age

6 months.[39] Enzyme activity corresponds. By age 1 to 6 months, production of the phenytoin metabolite 5-(4-hydroxyphenyl)-5-phenylhydantoin is comparable to that seen in adults.[43] In fact, CYP2C9 activity appears to supersede that observed in adults by age 3 to 10 years, declining to adult range by the conclusion of puberty.[43] This explains the frequent need for a relatively increased dose of phenytoin in this age group.

CYP2D6.

A number of drugs undergo biotransformation by CYP2D6, and some are more relevant to critically or chronically ill children than well children. Enzyme protein levels are undetectable in fetal liver except for those obtained from fetuses delivered by spontaneous or induced abortion. These specimens are far more likely to contain detectable enzyme, suggesting that parturition stimulates expression.[44] Enzyme activity, as evidenced by O-methylation of dextromethorphan, is negligible in fetal hepatic microsomes. Enzyme protein levels increase rapidly after birth, but the time at which they reach adult levels is variably reported in the literature. Levels in hepatic tissue from subjects aged 1 month to 5 years reportedly were only approximately two-thirds the adult levels,[5] but another study reported no difference in expression between patients younger than 1 year and those older than 1 year, suggesting that development of this isoform is complete by age 1 year.[45]

CYP3A4.

The CYP3A family comprises the largest fraction of measurable CYP-450 enzymes in adult liver.[5] In the fetal liver, CYP3A7 is the predominant isoform. After birth, there is a shift between CYP3A7 and CYP3A4, levels of which are negligible in fetal hepatic tissue. The mechanisms of this transition have not been elucidated. In infants and children, the activity of CYP3A4 is generally increased above that in adults. The biotransformation of carbamazepine demonstrates this developmental difference. Studies in children demonstrate that both clearance and production of the metabolite carbamazepine-10,11-epoxide significantly decrease with increasing age.[46-48] The role that other enzymes, particularly microsomal epoxide hydrolase, which further transforms carbamazepine-10,11-epoxide, play in these developmental differences is uncertain.[33] In addition, although these age-related differences have been described in pediatric patients on monotherapy, coadministration of anticonvulsants that are known to induce CYP3A4 are speculated to skew these findings. Nonetheless, these developmental differences in CYP3A4 activity have been suggested by study of other substrates, among them cyclosporine, which also exhibits increased clearance in children compared with adults.

The development of other phase I enzyme systems has been studied much less extensively. Alcohol dehydrogenase activity is detectable in 2-month fetuses at levels no greater than 3% to 4% of adult activity.[49] Moreover, the level of activity does not approach adult values until after age 5 years.

Aromatic nitroreductase activity is detectable in fetal livers by 7 to 8 weeks of gestation; however, the hepatic activity at midgestation remains low, and no specific postnatal pattern of development has been described. Also, few data exist on the ontogeny of hydrolytic enzymes. Echobichon and Stephens[50] found low levels of blood esterase activity in the fetus and neonate.

Biotransformation (Phase II Reactions)

Conjugation reactions, or phase II reactions, synthesize more water-soluble compounds by combining a substance with an endogenous molecule to enhance excretion of that substance. Glucuronide, sulfate, and glycine are the common endogenous molecules to which drugs are bound. A drug must possess a specific functional group, such as a carboxyl, hydroxyl, amine, or sulfhydryl, in order to be conjugated. Alternatively, a drug must acquire one of these functional groups by undergoing phase I metabolism. Phase II enzyme groups have been studied far less than CYP-450 enzymes; therefore the ontogeny of phase II enzymes remains relatively elusive.

Glucuronidation is the most common conjugation pathway because of the availability of glucuronic acid and the variety of functional groups with which it can combine. The uridine 5′-diphosphate glucuronosyltransferases (UGTs) participate in the biotransformation of at least 100 drugs (eg, acetaminophen, morphine, nonsteroidal antiinflammatory drugs [NSAIDs]) and endogenous compounds, including bilirubin and thyroxine. Ready elucidation of the ontogeny of UGT isoforms has been precluded by overlapping specificities. For a detailed summary of available information about the UGT enzyme family, the reader is referred to the review by de Wildt and coworkers.[51]

The activity of a number of UGTs is decreased in the fetus and neonate, as assessed by in vitro studies.[51-53] In addition, there is ample in vivo evidence of deficient glucuronidation in infants and particularly neonates. A profound example of this is the association of “gray baby syndrome” with the drug chloramphenicol, which normally undergoes glucuronidation. Morphine glucuronidation serves as a “probe” for isoform UGT2B7 activity. Studies have demonstrated significantly decreased clearance[54,55] and biotransformation[54] of morphine in neonates. Depending on how values are standardized between pediatric and adult subjects, morphine clearance approximates adult levels at anywhere from age 2 to 30 months.[5,55] Reduced UGT activity during infancy is also reflected in the biotransformation of acetaminophen. Levy and associates[56] demonstrated that 2- to 3-day-old term infants had a limited ability to conjugate acetaminophen with glucuronide, which is the major conjugation pathway in adults. However, this limitation in glucuronidation was compensated for by a well-developed sulfation pathway. This supports the findings of Alam and coworkers,[57] who showed that rates for glucuronidation are much lower and sulfation much higher with salicylamide and acetaminophen as substrates in children 7 to 10 years old compared with adults.

Studies evaluating bilirubin and chloramphenicol glucuronidation have reported low rates at birth, with adult rates achieved by age 3 years.[57] However, some evidence indicates that phenobarbital may induce glucuronidation in newborns and older children. Talafant and colleagues[58] administered phenobarbital 10 mg/kg/day to healthy full-term infants for their first 3 days of life. One group received phenobarbital intramuscularly and one group received phenobarbital orally; one group served as a control. These authors described significantly higher urinary glucaric acid concentrations on day 7 in the IM group than in the controls. This finding correlated well with a downward trend in serum bilirubin in the group receiving IM bilirubin. The ontogeny and potential substrates of other phase II enzymes are summarized in Table 124.3.

Additional Factors Affecting Hepatic Biotransformation

Several factors in addition to those of a developmental nature may affect hepatic biotransformation. Although the impact of each on hepatic enzyme systems is incompletely characterized, factors such as genetics, concomitant drug therapy, and critical illness may alter drug biotransformation and, hence, patient response. Genetic variation of a number of hepatic isoenzymes has been described, with corresponding variation in phenotype. For example, 7% to 8% of Caucasian children are characterized as "poor metabolizers" with reference to the enzyme CYP2D6, which may manifest as insufficient metabolism of several categories of drugs, including β-agonists, antidepressants, antipsychotics, antiarrhythmics, and derivatives of morphine.[33] Variants of CYP2C9 have been described, affecting metabolism of drugs such as tolbutamide, NSAIDs, warfarin, and phenytoin.[33] Polymorphism of the phase II enzyme *N*-acetyltransferase-2 (NAT2) affects half of the Caucasian and African-American populations in North America. In this case, "slow metabolizers" are at increased risk for several adverse drug responses, including drug-induced lupus erythematosus following procainamide or isoniazid therapy and Stevens-Johnson syndrome or toxic epidermal necrolysis following sulfonamide exposure.[33] Finally, several UGT isoforms are subject to genetic mutation. The best known of these genetic variations occur in UGT1 and UGT1A1, producing absent or reduced bilirubin glucuronidation in the case of the former isoenzyme and reduced bilirubin conjugation in the latter. Phenotypically, these mutations manifest as Crigler-Najjar and Gilbert syndrome, respectively. The effect of these UGT polymorphisms with respect to drug metabolism has not been substantially studied.[33] However, sparse data suggest that glucuronidation of drugs may also be affected in these patients.[33,59]

The frequent need for polytherapy in the ICU increases the possibility that hepatic biotransformative enzyme systems will be induced or inhibited, affecting the metabolism of any substrate of that system. Leeder and Kearns compiled a list of drugs known to induce or inhibit hepatic metabolic enzymes.[33] Even less is known about the effect of critical illness on hepatic enzyme function than that of development. Several factors may contribute to altered hepatic metabolism in critically ill patients. Decreases in cardiac output and, consequently, hepatic blood flow reduced clearance of lidocaine in adult patients; in these patients, treatment with dobutamine improved plasma clearance.[60] In vivo studies suggest that certain CYP isoforms, including those in the CYP3A family, are exquisitely vulnerable to hypoxia, demonstrating alteration of activity after as few as 8 hours of hypoxia.[60] The systemic inflammatory response appears to potentially alter CYP activity as well. Mice infected with *Listeria monocytogenes* experienced decreased expression of some CYP-450 enzymes, which returned to normal levels after 96 hours.[61] Many inflammatory mediators reduce expression of CYP isoforms, including CYP1A1, CYP2C, CYP2E1, and CYP3A in human hepatocytes.[62] Decreased metabolism of a number of known substrates of CYP-450 has been demonstrated in patients with fever induced by infection and drugs and with hypothermia following cardiopulmonary bypass.[60] Of course, linking pharmacokinetic variations in the critically ill patient to impaired hepatic metabolism is difficult in the face of other pathophysiologic alterations.

Drug Elimination

The elimination half-life ($t_{1/2}\beta$) of a drug is commonly used to describe its disappearance from the blood and is measured as the time required for half the amount of drug present in the blood to disappear. As such, $t_{1/2}\beta$ can be used to reflect drug clearance, although changes in V_d also affect this parameter. This and related pharmacokinetic principles are discussed more thoroughly later in the chapter.

Renal Excretion

Most drugs or their metabolites are excreted from the body by the kidneys. Renal excretion depends on glomerular filtration, tubular reabsorption, and tubular secretion.[63] The amount of drug that is filtered per unit of time is influenced by the extent of protein binding and renal plasma flow. When the latter is constant, the greater the extent of protein binding, and the smaller the fraction of circulating drug that is filtered. The degree of protein binding also influences drug elimination in patients undergoing dialysis in a similar manner; drugs that are highly protein bound are less easily dialyzed.[64,65] This section also examines developmental aspects of renal function and their influence on renal drug excretion.

Renal blood flow and renal plasma flow increase with age as a result of increased cardiac output and reduced peripheral vascular resistance.[66-68] The kidneys of neonates receive only 5% to 6% of the cardiac output compared with 15% to 25% in adults. Renal plasma flow averages 12 mL/min (0.72 L/hr) at birth and increases to 140 mL/min (8.4 L/hr) by age 1 year. If renal plasma flow is corrected for body surface area, adult values are reached before 30 weeks of extrauterine life. Using clearance of para-aminohippurate to estimate renal plasma flow, Calcagno and Rubin[69] demonstrated adult rates by age 5 months.

At birth, glomerular filtration rate (GFR) is directly proportional to gestational age.[70] However, a linear relationship is not evident before 34 weeks of gestation. Inulin clearance rates below 10 mL/min have been described in newborns under 34 weeks of gestation, reflecting a significantly reduced GFR. This process must be considered when administering drugs or fluid to the premature newborn.[70] At birth, GFR for term infants ranges from 2 to 4 mL/min. In the first 2 to 3 days of postnatal life, GFR in term babies increases markedly to rates between 8 and 20 mL/min. During the first several weeks of life, increases in GFR correlate with postconceptual age, not postnatal age.[70] Adult values for GFR (127 mL/min) are reached by age 2.5 to 5 months.[71] The postnatal increase in GFR most likely results from the combined effects of increased cardiac output, decreased peripheral vascular resistance, increased mean arterial blood pressure, increased surface area available for filtration, and increased membrane pore size.[72] In fact, the finding that increases in GFR correlate with postconceptual age suggests that maturational changes are an important factor in the observed increase in glomerular function. The clinical implications for maturation of GFR become apparent when considering drugs that are primarily eliminated by glomerular filtration. Several studies have investigated the pharmacokinetics of aminoglycosides in preterm and term infants. Szefler and colleagues[73] demonstrated a decreasing $t_{1/2}\beta$ for gentamicin with increasing gestational age in infants younger than 7 days.

Proximal convoluted tubules in the normal kidney of a full-term infant are small in relation to their corresponding glomeruli. This glomerulotubular size imbalance is reflected by functional differences in the transport capacity (secretion) of the

proximal tubular cells.[74] Therefore tubular function matures at a slower rate than does glomerular function. Reasons for this reduced functional capacity include not only the small size of the tubules but also a smaller mass of functioning tubular cells, reduced blood flow to the outer cortex, and immaturity of energy-supplying processes. This imbalance continues for the first year of life, after which function of both glomerular and tubular components is comparable to that in healthy, young adults.[75] Processes of both active absorption (ie, secretion) and passive absorption (ie, reabsorption) are impacted in the immature kidney.

Many drugs rely on either the organic anion or cation transport systems present in the proximal tubules for renal excretion. Penicillin is actively secreted. Results of pharmacokinetic studies of ampicillin, ticarcillin, benzylpenicillin, and methicillin show that the $t_{1/2}\beta$ for the penicillins varies inversely with gestational and postnatal age.[76-79] In all the studies cited here, $t_{1/2}\beta$ for penicillins was highly variable, but it generally decreased to 1 to 2 hours by 2 weeks postnatal age. These observations may be partially explained by findings in animals that the capacity of the pathways responsible for penicillin secretion may undergo substrate stimulation. Substrate stimulation has not been formally studied in human neonates, but evidence indicates that it does occur. Kaplan and associates[77] showed a reduction in $t_{1/2}\beta$ for ampicillin in both preterm and term infants after multiple doses compared with a single dose.

Furosemide is another drug secreted by the proximal tubules. In addition to being filtered, evidence for tubular secretion is inferred from adult data describing reduced rates of plasma clearance and urinary excretion after probenecid administration.[80] Aranda and colleagues[81] found an eightfold prolongation in $t_{1/2}\beta$ and an eightfold reduction in the elimination rate constant for furosemide in fluid-overloaded term and preterm neonates with normal renal function compared with adults. Peterson and coworkers[82] evaluated single-dose kinetics for furosemide in preterm and term infants and found a mean $t_{1/2}\beta$ of 19.9 and 7.7 hours, respectively. This is in contrast to a $t_{1/2}\beta$ of 30 minutes in healthy adults. These prolonged plasma half-lives correspond with the prolonged duration of diuretic and saluretic effect seen in infants,[83] although the response to furosemide most likely is dependent on its rate of urinary excretion.

The sensitivity of the kidney to hypoxic and ischemic insult is well known. Because this is one of the most important final common pathways for serious illness in infants and children, it follows that renal functional impairment is relatively frequent in patients in the PICU. Kidney function may be further impaired by the frequent use of nephrotoxic drugs such as amphotericin B and aminoglycosides in PICU patients. Clearly, varying degrees of renal functional impairment seen in critically ill infants and children can seriously complicate drug therapy in this setting.[84,85]

Drug Delivery Systems

As discussed previously, the maintenance of steady-state drug concentration requires that the amount of drug being administered match the amount of drug being cleared from the body. Several factors determine how much of a drug can be administered to any given patient at any given time. Although uncommon in the ICU, the available routes of administration may limit bioavailability and, hence, ultimate drug concentration. In the patient who requires fluid restriction, limitations

in the maximal concentration of drugs may prove problematic. In the smallest of patients, full delivery of intravenous drug doses contained in diminutive volumes of vehicle may not be assured. Administration of a drug as a bolus generally ensures that the patient has received the full dose, provided any tubing between the site where the drug is given and where it enters the vein is adequately flushed. In the case of drugs given over a discrete interval or by continuous infusion, the drug delivery system influences the amount of a given drug dose received by the patient. Regardless of the technology used, the amount of drug delivered by a system depends upon the designated flow rate and the amount of tubing between where the drug is introduced and the patient's bloodstream.[20] When a drug is added to a fluid reservoir, delivery also depends on the volume of drug added.[20] An example of the impact of these factors on drug delivery is as follows. If a drug is added to the reservoir in a system where the flow rate is 25 mL/hr, drug delivery may not begin for almost 2 hours and would require nearly 4 hours for completion.[20] Consequently, administering drug in this manner could result in delayed or incomplete drug delivery. Additionally, an inability to pin down the timing of drug delivery complicates interpretation of drug levels when monitored.[20]

Fortunately, considerable advances in drug delivery technology have been made since the 1990s[86] and have been of particular benefit in the PICU. Infusion pumps that provide greater volumetric accuracy have facilitated full delivery of small volumes. In some cases, improvements in infusion continuity have enabled uninterrupted delivery of continuously administered drugs, a fact that is of particular importance for drugs with very short $t_{1/2}\beta$ values (eg, nitroprusside).[86] It is important that the intensivist have some familiarity with the technology used in his or her unit; this knowledge may be helpful when an unintended response to pharmacotherapy occurs. For a comprehensive review of this technology, the reader is referred to the chapter by Kwan.[86]

Effect of Extracorporeal Therapies on Drug Disposition

Extracorporeal therapies, including hemofiltration, dialysis, and extracorporeal membrane oxygenation (ECMO), can alter drug disposition in affected critically ill patients. Although relatively little study has been devoted to drug disposition in patients on ECMO, evidence supports the idea that this treatment modality alters pharmacokinetics. In neonates and infants, the largest number of studies have looked at the disposition of gentamicin and vancomycin.[87] Increased V_d, increased $t_{1/2}$, and decreased clearance compared with control or post-ECMO values were demonstrated in the majority of these studies.[87-89] In one study investigating vancomycin, only an increased $t_{1/2}$ differentiated ECMO patients from non-ECMO controls.[90] Other drugs, including theophylline,[91] morphine,[92,93] tobramycin,[87] bumetanide,[87] and ranitidine,[87] have been shown to increase V_d, decrease clearance or increase $t_{1/2}$ in patients on ECMO. The addition of an extracorporeal reservoir contributes to the increase in V_d, and alterations in hepatic and renal function in ECMO patients impact clearance. Additionally, adhesion of some drugs to circuit hardware may alter serum or blood concentrations. The age of the circuit appears to influence this factor to some extent. Dagan and colleagues[93] evaluated the "elimination" of drugs following direct injection into two circuits: a new one and a circuit that had been used by a patient for 5 days. A relatively increased elimination

of several drugs by the new circuit was described (vancomycin, 36% versus 11%; gentamicin, 10% versus 0%; phenobarbital, 17% versus 6%; phenytoin, 43% versus 0%; morphine, 36% versus 16% in the new versus used circuit).[93] Several other drugs are subject to this phenomenon, including heparin, furosemide, fentanyl, benzodiazepines, propofol, and perhaps morphine.[87] Propofol appears particularly susceptible to this effect. In vitro studies using entire circuits and various individual components report recovery of propofol has been 10% or less.[87] In the in vitro studies, priming of the circuit with albumin appears to reduce adsorption of at least some of these drugs.[87] This method of priming may have contributed to the maintenance of serum morphine concentrations in an in vivo study as well.[94] Drug concentrations may be altered when a circuit containing some fraction of that drug is discarded and replaced.[87] Finally, pharmacokinetics may be altered by in-line hemofiltration, which is required in approximately 12% of neonates on ECMO, and by dialysis, which is required by approximately 3% to 4% of these patients.[87]

Pharmacodynamics

In contrast to pharmacokinetics, which operationally describes what the body does to the drug, pharmacodynamics deals with what the drug does to the body.[95] As such, this discipline within pharmacology deals with the mechanisms of action of drugs, their safety profiles, drug-receptor interactions, and receptor-effector coupling phenomena. Infants and children have been described to exhibit different clinical responses to several medications than do adults. One example of this difference is the hyperexcitability children may experience following exposure to antihistamines and barbiturates in contrast to the sedation normally observed in adults.[96] Children also have a greater incidence of dystonic reactions following the administration of dopamine antagonists (eg, haloperidol, chlorpromazine, metoclopramide), which has been speculated to result from an increased concentration of DA-2 receptors in the young brain.[96] When no pharmacokinetic explanation for different drug responses between children and adults has been offered, a difference in "sensitivity" has been proclaimed. Variable sensitivity to drugs, including some of the nondepolarizing neuromuscular blocking agents (eg, pancuronium) and the catecholamines, has been described in infants compared with adults. For example, a decreased sensitivity to dopamine has been observed in infants, manifested by an insignificant change in any physiologic variable (including heart rate) below a dose of 15 μg/kg/min.[96] The formal study of ligand-receptor interactions and their consequences is covered comprehensively in two referenced texts.[97,98] However, the translation of these principles into the practice of medicine is embodied in the discipline of therapeutics. Just as important developmental changes determine the related absorption, distribution, metabolism, and excretion of drugs, ontogenetic changes in drug responsiveness account for both the qualitative and quantitative differences observed in efficacy and toxicity when drugs are used in infants and children. Unfortunately, the latter have not been evaluated with the same intensity that has characterized our assessment of developmental changes in pharmacokinetics.[99,100] Actions of drugs in the immature individual may be altered for a variety of reasons, including altered numbers of receptor sites compared with mature individuals, altered affinity of the receptor for its primary ligand or agonists, or altered receptor-effector coupling resulting in altered drug responsiveness.

Additional work is necessary to bring this level of sophistication to the clinical setting.

Effect of Disease on Drug Action

During serious illness, substantial changes may occur in receptor function, tissue architecture, and postreceptor function that ultimately are responsible for changes in drug action. These often result from vascular volume or electrolyte derangements and from the effects associated with derangements in acid-base status. Nevertheless, conditions such as pulmonary fibrosis and cardiomyopathy may be associated with diminished responsiveness to drugs acting on the affected organ. Infection with *Haemophilus influenzae* type B has been associated with decreased pulmonary β_2-receptor function with a resultant increase in airway resistance.[101,102] Protracted use of catecholamines may result in downregulation of functional β-receptors in target organs, requiring frequent dose increases to achieve the maintained desired pharmacologic effect.[103-105]

Finally, remember that most drugs used in the PICU are potent agents that have the potential to cause serious side effects.[106] Unfortunately, drug toxicity in a critically ill patient may be an amplified event. Such patients are the least likely to be able to tolerate such effects. Thus the therapeutic index for most of the drugs used commonly becomes increasingly narrow as the patient's condition warrants more aggressive therapy.[107]

Pharmacokinetic Principles

Evaluation of the Plasma Concentration-Time Curve

The application of pharmacokinetic principles to patient care should permit rational drug dosing and result in effective pharmacotherapy. Most of the drugs used in clinical medicine are metabolized via linear first-order kinetic processes (Fig. 124.2). This means that a constant percentage of drug is removed from the body per unit of time. Virtually all of the pharmacokinetic parameters used on a routine basis can be derived from a plot of serum/plasma concentration versus time, which then is converted to a semilogarithmic display (Fig. 124.3). The straight, terminal portion of the former represents the elimination phase for the drug, and its slope is the elimination rate constant K_e (Table 124.3 and Fig. 124.4). The elimination half-life for the drug $t_{1/2}\beta$ (see Fig. 124.2) then can be determined directly by inspection of the semilogarithmic graph as the time required for the concentration to decrease by half, or it may be calculated from the exponential decay curve considerations once K_e is determined:

$$t_{1/2\beta} = \frac{0.693}{K_e}$$

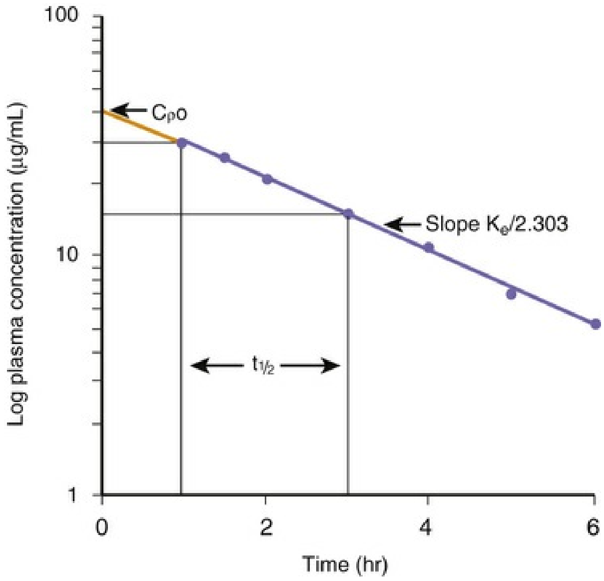

FIG. 124.2 First-order elimination. Plasma concentration versus time curve for a drug eliminated via first-order kinetics. Note the elimination half-life is depicted as the time required for the drug concentration to be reduced by half. A constant fraction of the drug in the body is eliminated in each equal interval of time.

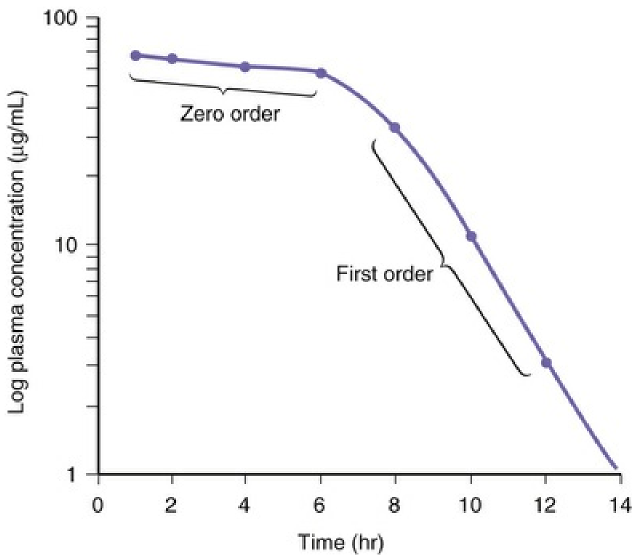

FIG. 124.3 Michaelis-Menten kinetics. Log plasma concentration versus time curve for a drug showing saturation of the elimination mechanism. Initially, a constant amount of drug is eliminated per unit time rather than a constant fraction of drug per unit time. This initial phase is said to show zero-order elimination. Later, the plasma concentration falls below the saturating level and the elimination process becomes first order.

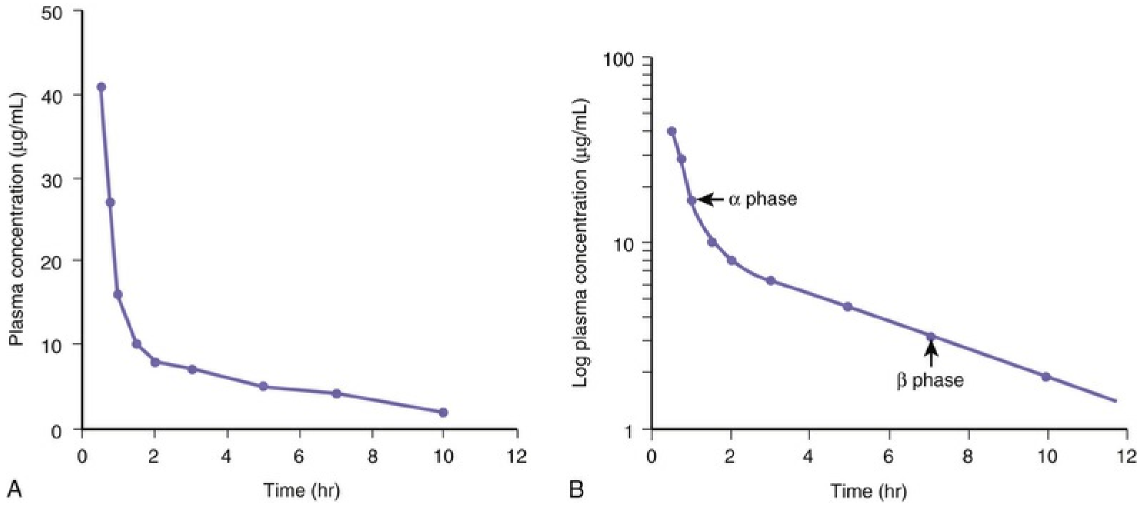

FIG. 124.4 Two-compartment model. (A) Plasma concentration versus time curve presented using rectangular coordinates. (B) Semilogarithmic transformation of the data shows a biphasic curve rather than a straight line. This is thought to represent the interaction between two compartments: plasma and extracellular fluid space. The upper portion of the curve is called the *α phase* and is thought to represent drug distribution. The lower portion is termed the *β phase* and is thought to represent actual drug elimination. Slope of the β phase = −K/2.303.

The area under the serum concentration versus time curve (AUC) can be determined by applying an approximate integration formula, most commonly the trapezoidal rule.[108] This method involves the description of a given plasma concentration-time curve as a series of straight lines, which enables the curve to be divided into a number of trapezoids (Fig. 124.5). The area of each trapezoid can be easily calculated, and the sum of all such areas equals the area under the AUC. The latter value is important in deriving two other values of clinical importance: bioavailability and clearance of the drug. Finally, by extrapolating the terminal elimination phase of the curve b to time 0, the intercept on the y-axis denotes the concentration that would have resulted if the total dose of the drug had instantaneously distributed throughout the body (Fig. 124.6). This concentration, termed C_o, can be used to determine the apparent volume of distribution of the drug V_d, using the following equation:

$$V_d = \frac{D}{C_o}$$

where *D* is the dose administered.

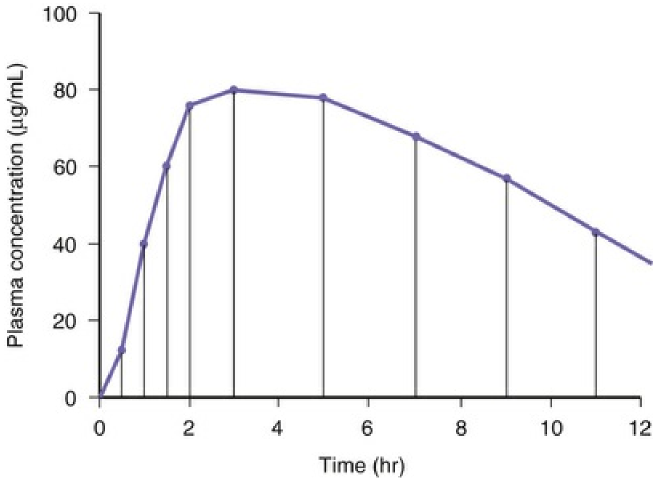

FIG. 124.5 Trapezoidal rule. Plasma concentration versus time curve for a drug after oral administration. The area under the curve (AUC) represents the total amount of an individual dose that is absorbed. This area can be calculated by dividing the curve into a series of trapezoids, calculating the area for each, and summing all of the areas.

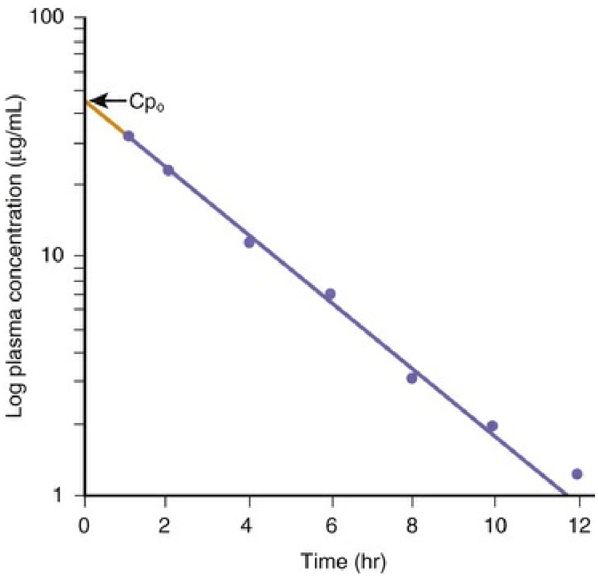

FIG. 124.6 Log plasma concentration versus time curve depicting Cp_o. This is a semilogarithmic plot of plasma drug concentration versus time after intravenous infusion of drug. This drug shows one-compartment, first-order elimination as indicated by the single straight line. Extrapolation of the line back to time zero yields an estimate of Cp_o or the drug concentration that would result if the total dose were administered and distributed immediately throughout the body. If the dose administered is known and the C_o ascertained, the apparent volume of distribution V_d of the drug administered can be calculated.

In children, a number of important compounds demonstrate saturation kinetics at clinically useful doses (Box 124.5). In this case, the drugs appear to have longer half-lives at higher concentrations. For these drugs, the relationship between serum concentration and time is better described by the values V_{max} and K_m than by V_d and

Cl.[18,109] The most important drug demonstrating this type of biodisposition is phenytoin.[110] With this drug, a small increase in dose may result in a large increase in serum concentration. Disease states and drug interactions can pose particular problems for patients receiving drugs cleared by saturable processes. A patient with liver dysfunction may have decreased V_{max} for a given drug compared with a healthy child. Consequently, saturation of metabolic elimination may occur at a lower concentration than normal.

Salicylate

Applied Pharmacokinetics

Use of pharmacokinetic parameter estimates is essential to the development of proper dosing regimens, the effective use of the drug analysis laboratory, and ultimately in optimization of drug therapy. Among the available parameters, the most important in the PICU are clearance (Cl), volume of distribution (V_d), and half-life ($t_{1/2}\beta$). In addition, if oral therapy is contemplated, bioavailability (F) must be considered. Each of these parameters can be used for mathematically describing the biodisposition of a drug under steady-state conditions.

Bioavailability

The concept of bioavailability was discussed extensively in the section related to drug absorption. For most drugs administered intravenously, the bioavailability is 100% and F = 1. In clinical terms, the *relative* bioavailability of a drug is most important. Bioavailability F is defined as the ratio of the AUC for the drug given by a nonintravenous route (AUC_{Oral}) to the AUC of the same drug administered intravenously (AUC_{IV}):

$$F = \frac{AUC_{Oral}}{AUC_{IV}}$$

Relative bioavailability can be used to convert from one route of administration to another. For example, the relative bioavailability of theophylline is 1. Therefore in switching from intravenous to oral dosing, the same total daily dose of theophylline should be administered. In contrast, the relative bioavailability of furosemide is approximately 0.5. Thus in switching from intravenous to oral administration, the dose of the drug should be doubled to maintain the same diuretic effect.

Half-Life

Elimination half-life of a drug is a hybrid term that is a function of both clearance and volume of distribution:

$$t_{1/2\beta} = \frac{0.693}{K_e} = \frac{0.693V_c}{Cl}$$

This is the pharmacokinetic parameter most commonly used by clinicians, but it is often misconstrued to signify drug elimination. However, as shown in the equation, either a change in Cl or a change in V_d can result in a change in $t_{1/2}\beta$. The therapeutic implications of these alterations are clearly different. It is also apparent that if pathophysiologic changes result in offsetting changes in V_d and Cl, the elimination half-life could remain unaffected in the face of significant disease. The most important clinical application of half-life is as a determinant of drug dosing. Four to five half-lives are required for a drug to reach a steady-state plasma concentration at any given dose. This is true whether therapy is being initiated or the dose is being changed.

Apparent Volume of Distribution

The volume of distribution V_d describes the apparent volume of the compartment into which the drug distributes. It must be emphasized that this value has no physiologic significance. Rather, it serves as a parameter estimate that permits the calculation of the dose of drug (ie, loading dose) required to achieve a desired plasma concentration:

$$C_p = \frac{Dose}{V_d}$$

It should be noted that calculation is independent of the drug's clearance and half-life.

Total Body Clearance

As previously noted, clearance is a useful parameter for determining the amount of drug needed to maintain a desired steady-state plasma concentration. Because by definition the rate of drug elimination at steady state is equal to the rate of drug

administration, then[19,31,108]

$$\text{Elimination rate} = C_p \times Cl$$

where C_p is the average steady-state plasma concentration:

$$\text{Administration rate} = (F \times D)/\tau$$

where D = dose and τ = dosing interval.

At steady state:

$$C_p \times Cl = (F \times D)/\tau$$

or, rearranging:

$$C_p = (F \times D)/(Cl \times \tau)$$

where the solutions provide the average steady-state plasma concentration. It is obvious from the equation that to maintain a steady-state plasma concentration, disease-associated changes in Cl must be compensated by changes in dose D or interval τ.

Critical Care Therapeutics

In the treatment of critically ill infants or children, consideration must be given to both developmental and disease processes. Thus at first glance it seems an overwhelming task to develop therapeutic strategies that would be both safe and effective in treating these patients. Nevertheless, two approaches can be identified that lend themselves to the rational care of these patients: target concentration strategy and target effect strategy.[111]

Target Concentration Strategy

The target concentration strategy can be considered for drugs that are used chronically to treat clinical problems that manifest themselves intermittently (Box 124.6). Such problems include reversible reactive airway disease, seizures, and cardiac dysrhythmias. Application of this therapeutic strategy requires recognition that certain target serum concentrations are associated with either the therapeutic or the toxic effects attributed to a given pharmacologic agent. It is important to remember that these target concentration ranges are determined using population-based data rather than individual patient data. Therefore the so-called therapeutic or toxic ranges may not be strictly applicable to the patient currently being treated. However, they serve as useful guides for the initiation and ongoing monitoring of therapy. As part of this ongoing monitoring, effective use of the drug analysis laboratory is essential. To apply the target concentration strategy, physicians must

have some knowledge of the pharmacokinetics of the drug being used (Box 124.7). Such knowledge includes an awareness of any active metabolites that may be involved in the expression of the drug's therapeutic activity.

Box 124.6

Principles of the Target Concentration Strategy in Drug Therapy

- Strategy may be effective for drugs used on a chronic basis to treat diseases that manifest signs and symptoms intermittently.
- Caregivers must have some knowledge of the pharmacokinetics of the drugs being used.
- A relationship between drug or metabolite concentration in the sampled biological fluid and therapeutic efficacy or clinical toxicity must have been established.
- Appropriate sampling time must be known and a reliable assay must be available.
- **Target concentrations must be used as guides; treat patients, not drug levels.**

Box 124.7

Drugs Used in the Target Concentration Strategy

Antiarrhythmic agents: amiodarone, procainamide, quinidine, lidocaine

Anticonvulsant agents: phenytoin, phenobarbital, valproic acid, carbamazepine, pentobarbital

Antibiotics: aminoglycosides, chloramphenicol, vancomycin (±)

Methotrexate

Cyclosporine

Antipyretics: acetaminophen, salicylate

Theophylline

The approach to treatment of the patient in whom the target concentration strategy is to be used requires that the physician have an expectation regarding the clinical manifestations of drug efficacy and drug toxicity before any therapy is initiated. This should be accompanied by an awareness of the appropriate sampling times for the various drugs and an overall understanding that drug “levels” are guides to therapy rather than therapeutic end points in themselves. Therapeutic drug monitoring does not substitute for other means of patient evaluation. Effective drug dosing using the target concentration strategy requires a familiarity with the pharmacokinetic parameters previously described and the effective use of the drug

analysis laboratory. When a target plasma concentration is known, an initial dose can be chosen. Under some circumstances, it may be desirable to achieve the target concentration immediately. In these instances, the initial dose is termed a *loading dose* and calculated as follows:

$$\text{Loading dose} = \frac{C_p \times V_d}{F}$$

where C_p is the target concentration.

Use of a loading dose is not always appropriate. Under certain circumstances, the calculated loading dose can result in toxic plasma concentrations before tissue distribution. The alternative is to begin therapy with what is termed the *maintenance dose:*

$$\text{Maintenance dose} = \frac{C_p \times \tau \times V_d}{F}$$

When therapy is initiated with a maintenance dose, dosing for a total of four to five half-lives will be required to reach the desired steady-state plasma concentration. In contrast, when used in conjunction with a loading dose, the maintenance dose should maintain the plasma concentration attained with the loading dose.

Effective use of therapeutic drug monitoring in the critical care setting requires integration of certain characteristics of the drugs to be used, the laboratory where drug analysis occurs, and physician behavior. The drug selected for therapeutic drug monitoring should be one from which a relatively sustained and constant effect is expected over a comparatively long period of time. Monitoring should be limited to drugs characterized by wide interindividual variation in pharmacokinetics, as well as those that manifest a narrow therapeutic index. Finally, it is imperative that a set of data exists to relate the clinical effects of the drug directly to its concentration in the serum.

For drugs fulfilling these criteria, sensitive and specific assays for determination of their concentrations in various types of biological fluids must be available. Moreover, this service must be provided with a turnaround time that is appropriate to the type of therapy being rendered. Thus it may be appropriate to provide aminoglycoside serum concentration determinations with a 24-hour reporting schedule; however, the safe and effective adjustment of theophylline dosing requires that serum concentrations be available within 1 hour from the time the blood is drawn. In addition, the results provided by any laboratory must be internally consistent. Standard curves must be checked frequently, and this quality assurance information must be available to all physicians upon request.

Use of the target concentration strategy places heavy demands on the physician. Values for commonly used pharmacokinetic parameters describing absorption, distribution, and elimination should be known or readily available. The physician must be aware of conditions in which these pharmacokinetic parameter estimates may be altered and the extent to which these alterations may affect therapy. The

physician must have a working knowledge of the average steady-state concentrations of drug in serum associated with both drug effectiveness and drug toxicity. Moreover, the pathophysiologic conditions that may alter these concentration-response relationships must be understood. Finally, clinical experience and sound judgment must prevail. Therapy must consist of an ongoing commitment to treat patients and not drug levels.

Target Effect Strategy

The target effect strategy embodies the therapeutic approach most commonly practiced in the PICU. In fact, the therapeutic strategy allows for rational application of most of the drug classes required in the intensive care setting to the pediatric patient (Box 124.8). Application of the target effect strategy requires that the clinician determine a therapeutic end point before initiating drug treatment and accept a commitment to monitor for both drug effectiveness and toxicity. In using this approach, the clinician must have a reasonable understanding of the pharmacodynamic actions of the drugs to be used, including their side-effect profiles. Moreover, the impact of both ontogeny and disease on drug action must be considered. Once therapy is started, the dose is increased until the desired effect is achieved, unless the sequential increase in drug dose results in no increase in therapeutic benefit and the desired effect is not achieved or drug toxicity supervenes. The amount of time taken in dosage escalation is dictated by the clinical circumstance at hand. In some circumstances, days of adjustments may be acceptable, whereas in others minutes may be too long. Nevertheless, inherent in this strategy is a belief that responses to drugs are dose related and that any concept of a preexisting maximal dose is precluded. Thus if either lack of efficacy or toxicity becomes apparent, the mandated response is to *change* the drug.

Box 124.8

Classes of Drugs Used in the Target Effect Strategy for Critically Ill Children

Anticoagulants

Catecholamines

β-Lactam antibiotics

Diuretics

Corticosteroids

Oxygen

Anxiolytics, sedatives

Neuromuscular blockers

Vasodilators
Antihypertensives
Inotropes: amrinone

In summary, rational therapeutics for the critically ill child must account for the impact of development and disease on drug action. The scenario suggests use of short-acting drugs with large therapeutic indexes and requires that expectations regarding drug effects be ascertained prospectively. This approach mandates rigorous attention to monitoring but ultimately ensures that the dosage used will be sufficient to achieve the desired response.

CHAPTER 125

Molecular Mechanisms of Drug Actions

From Receptors to Effectors

Catherine Litalien, Pierre Beaulieu

PEARLS

- Receptors play a central role in determining the nature of the pharmacologic effects produced by a drug.
- Most drugs and endogenous compounds (eg, hormones, neurotransmitters) exert their action by binding to a receptor or by modulating an ion channel.
- G proteins are a superfamily of proteins that allow transduction between an activated receptor (by an agonist) and different intracellular effectors, such as enzymes or ion channels, relaying signals from more than 1000 receptors. G protein–coupled receptors are complex signaling machines that participate in most physiologic and pathophysiologic processes and represent the target, directly or indirectly, of approximately 40% of all current therapeutic agents. Continued exposure of a receptor to an agonist often results in progressive loss of receptor responsiveness, with a diminished receptor-mediated response over time. This is called *desensitization*.
- Two main superfamilies of membrane transporters provide the active transport of drugs to their target receptors in specific organs and tissues: the adenosine triphosphate–binding cassette superfamily and the solute carrier family.
- Calcium is critically important as a regulator of cell function. It exerts its control on cellular function through its ability to regulate the activity of many different proteins, such as channels, transporters, and transcription factors. In the majority of cases, a calcium-binding protein serves as an intermediate between Ca^{2+} and the regulated functional protein.
- An individual's genetic makeup can modify the efficacy of drug treatment and the risk of adverse reactions. The role of inheritance in the individual variation of drug response is increasingly recognized with the identification of polymorphisms in genes encoding drug-metabolizing enzymes, drug targets, and proteins involved in signal transduction. However, most of these have not

translated into pharmacogenetics-based therapy, as multiple factors beyond genetic variability have the potential to influence drug response, even more so in the critically ill patient. Mathematic models and systems biology capable of integrating all of these variables may prove more useful to adequately predict drug response.

Optimizing drug response is a challenging task that clinicians confront on a daily basis. This is particularly true for those caring for critically ill patients, in whom many factors influencing drug response are being more commonly recognized. These include reduced absorption, variable drug distribution, decreased metabolism and elimination, as well as alterations in drug receptors, signaling mechanisms, and effectors.[1-3] Advances in molecular pharmacology have shed more light on the processes that transduce extracellular signals into intracellular messages that control cell function. This has led to the elucidation of multiple points at which modulation of signal transduction, by either pharmacologic agents or diseases, can occur. Also, there has been an ongoing recognition of the role of inheritance in the individual variation of drug response with the identification of polymorphisms in genes encoding drug-metabolizing enzymes, drug targets (eg, receptors, enzymes), and proteins involved in signal transduction.[4-6]

This chapter provides a detailed overview of how drugs work at the molecular level and how this complex system is influenced by genetic factors, developmental changes, disease processes, and the environment (Fig. 125.1). Ultimately, the objective is to help pediatric intensive care physicians better tailor the pharmacotherapy they use—that is, choose the right drug, or combination of drugs, for the right patient to achieve maximal efficacy with no or minimal toxicity. This chapter does not address signaling pathways involved in diseases per se.

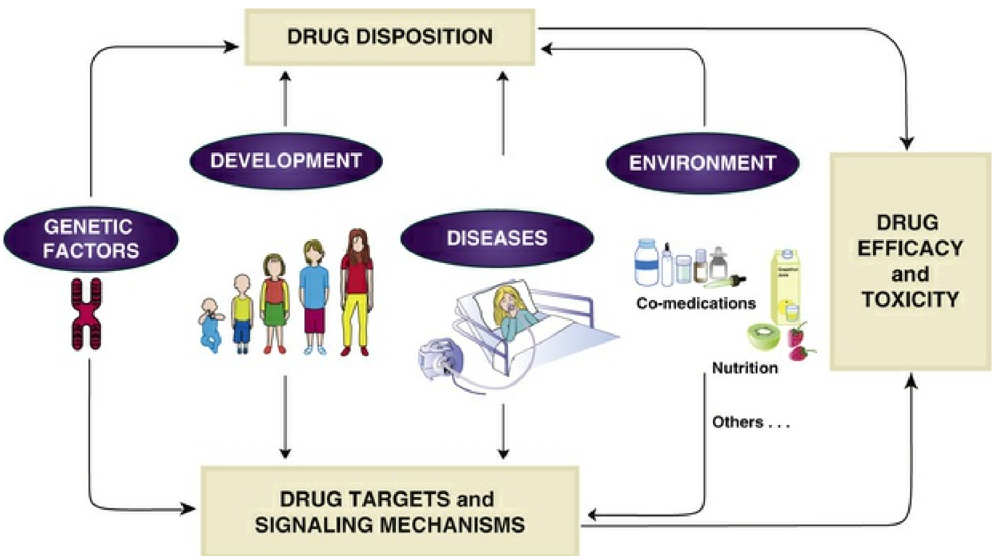

FIG. 125.1 Relationships among genetic factors, development, diseases, and the environment and drug efficacy and toxicity.

Targets for Drug Action

The initial step in the cascade of biochemical events resulting in drug action mostly consists in the binding of drugs to specific cellular targets. These can be broadly divided into four categories: (1) receptors, (2) ion channels, (3) enzymes, and (4) carrier proteins (Fig. 125.2). The majority of important drugs act on one of these types of proteins. Table 125.1 shows the targets of some pharmacologic agents commonly used in the pediatric intensive care unit.

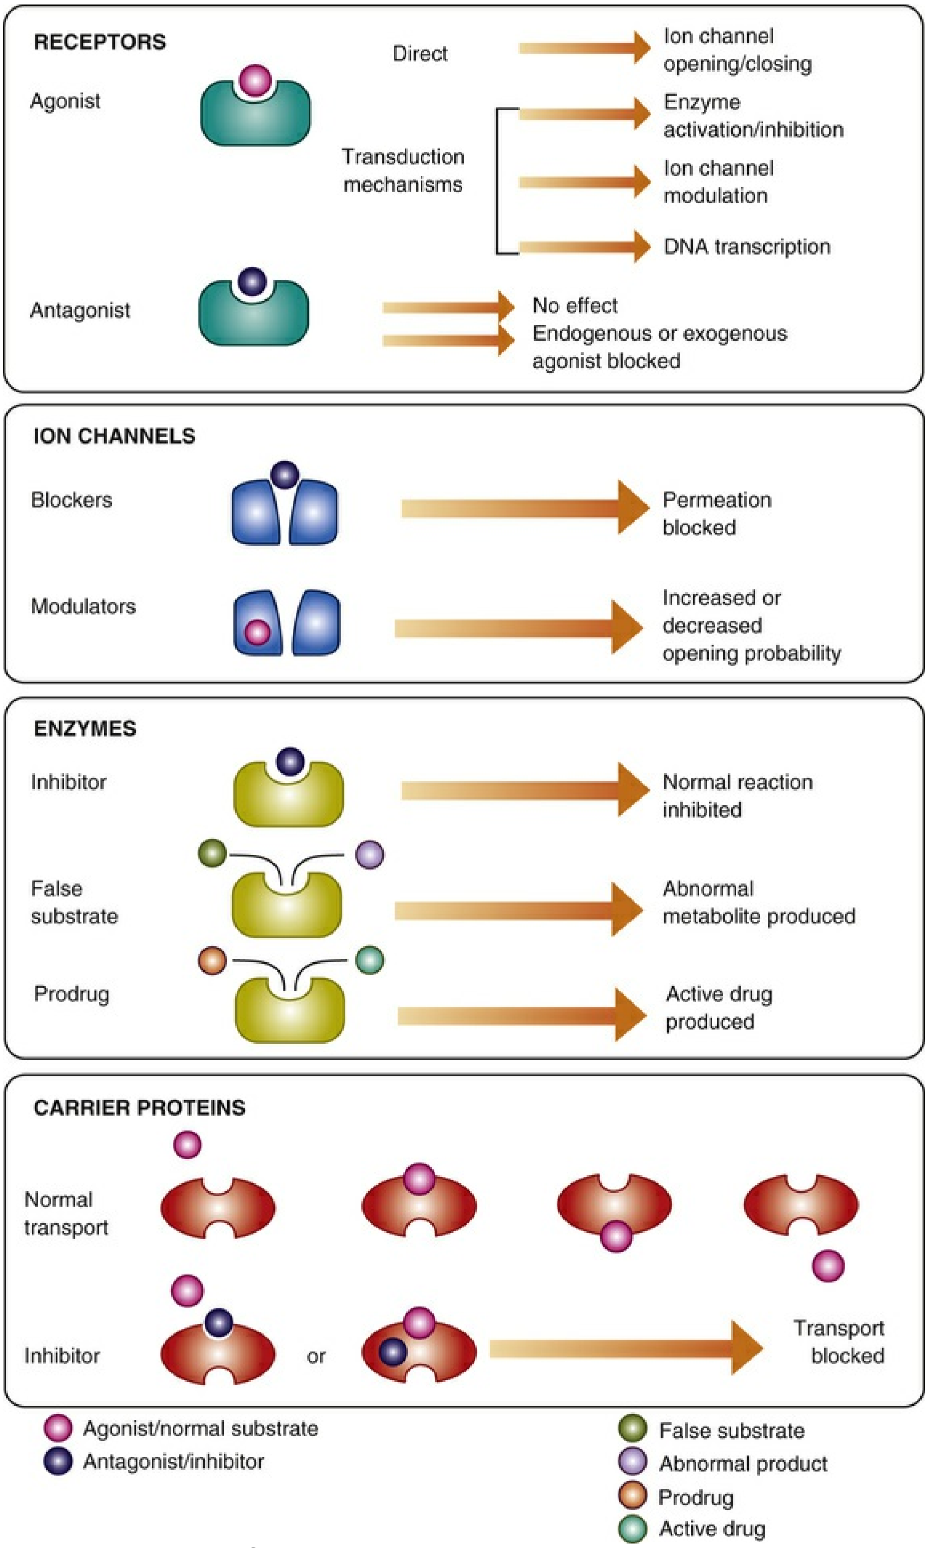

FIG. 125.2 Targets for drug action. (Modified from Rang HP, Dale MM, Ritter JM, et al. Rang and Dale's Pharmacology. 7th ed. Philadelphia: Churchill Livingstone; 2012.)

TABLE 125.1
Targets of Drugs Commonly Used in Critically Ill Children

Drug	Target	Agonist	Antagonist

Receptors			
G Protein–Coupled Receptors			
Adenosine	Adenosine	√	
Atropine	Muscarinic		√
Bosentan	ET_A, ET_B		√
Clonidine	α_2-adrenergic	√	
Dopamine	D_1	√	
Dopamine	α- and β-adrenergic	√	
Dobutamine	β-adrenergic	√	
Epinephrine	α- and β-adrenergic	√	
Haloperidol	D_2		√
Isoproterenol	β-adrenergic	√	
Neuromuscular blockers (depolarizing and nondepolarizing)	Nicotinic		√
Norepinephrine	α- and β-adrenergic	√	
Opioids	μ, δ, κ Opioid	√	√
Phenoxybenzamine	α-adrenergic		√
Phenylephrine	α_1-adrenergic	√	
Propranolol	β-adrenergic		√
Ranitidine	H_2		√
Vasopressin	V_1, V_2, V_3	√	
Salbutamol	β_2-adrenergic	√	
Channel-Linked Receptors			
Barbiturates	$GABA_A$-gated Cl^-	√	
Benzodiazepines	$GABA_A$-gated Cl^-	√	
Flumazenil	$GABA_A$-gated Cl^-		√
Ketamine	Glutamate-gated (NMDA) cation		√
Enzyme-Linked Receptors			
Nitric oxide	Soluble guanylate cyclase	√	
Insulin	Insulin	√	
Nuclear Receptors			
Glucocorticoids	Glucocorticoid	√	
Spironolactone	Mineralocorticoid		√
Ion Channels			
Adenosine	Ca^{2+}		√
Amiodarone	Na^+, K^+, Ca^{2+}		√
Lidocaine	Na^+		√
Enzymes			
Acetazolamide	Carbonic anhydrase		√
Captopril	Angiotensin-converting enzyme (peptidyl dipeptidase)		√
Milrinone	Phosphodiesterase III		√
Nonsteroidal antiinflammatory drugs	Cyclooxygenase-1 and -2		√
Sildenafil	Phosphodiesterase V		√
Ion Pumps and Transporters			
Digoxin	Na^+/K^+-ATPase pump		√
Loops diuretics	$Na^+/K^+/Cl^-$ cotransporter		√
Omeprazole	H^+/K^+-ATPase pump		√
Thiazides	Na^+/Cl^- cotransporter		√

D, dopaminergic; *ET*, endothelin; *GABA*, γ-aminobutyric acid; *H*, histamine; *NMDA*, *N*-methyl-D-aspartate; *V*, vasopressin.

Receptors

Receptors are the most frequent drug target. They can be defined as the sensing elements in the system of chemical communication that coordinate the function of all different cells in the body, the chemical messengers being the various hormones, neurotransmitters, other mediators, or drugs. Ligands (eg, hormones, drugs) that bind with receptors are termed *agonists* if their binding results in the expected effect and are termed *antagonists* if binding stops or decreases an agonist-induced activity.[7] Administration of a receptor antagonist in the absence of an agonist results in no

effect because antagonists bind to receptors but do not activate them. *Competitive antagonism* (surmountable or reversible) is when a drug with affinity for a receptor but lacking intrinsic efficacy competes with the agonist for the primary binding site on the receptor. In such an antagonism, there is a concentration-dependent production of a parallel shift to the right of the agonist dose-response curve with no change in the maximal response.[8] In the case of *noncompetitive antagonism* (insurmountable or irreversible) with a slowly dissociating or nondissociating antagonist, there is a shift of the dose-response curve to the right and a further depression of the maximal response; no change in the antagonist occupancy takes place when the agonist is applied (Fig. 125.3A).

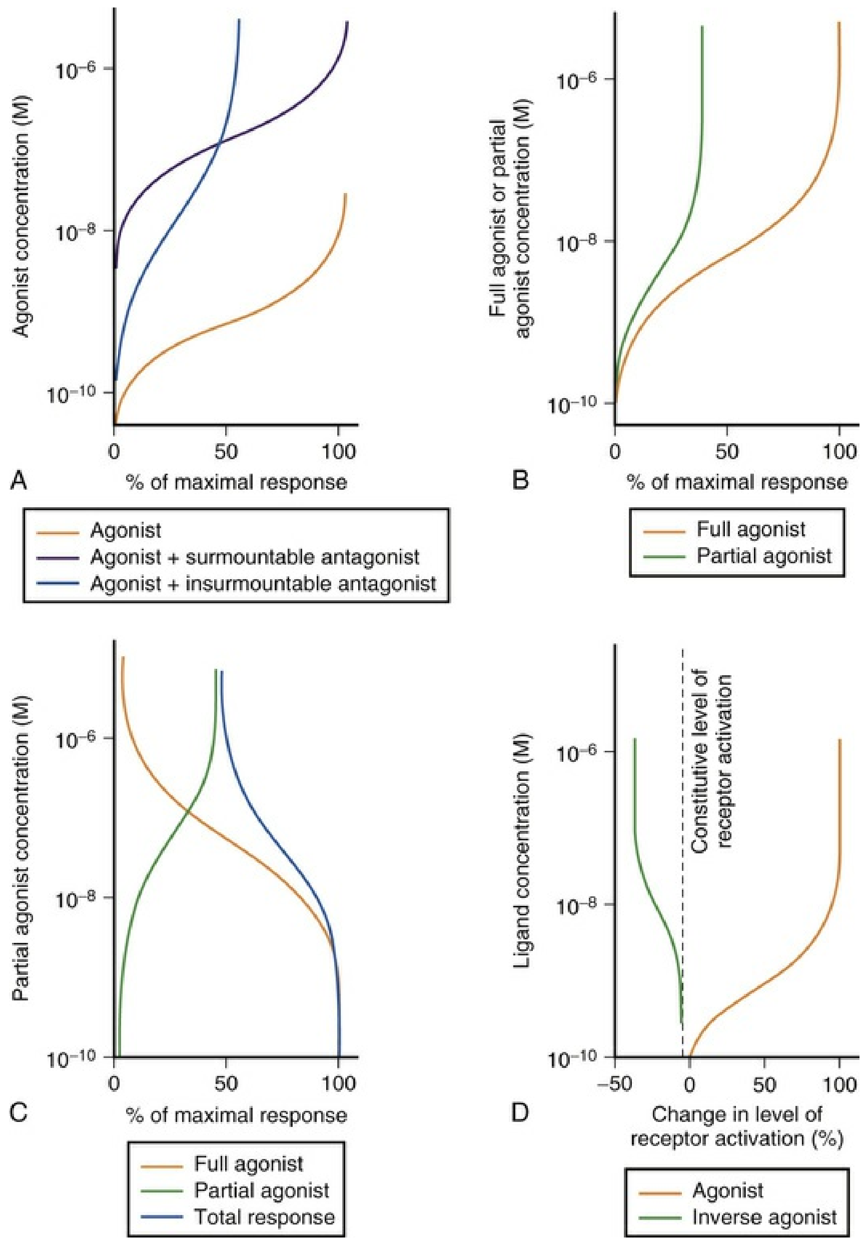

FIG.125.3 (A) Concentration-response curves for an agonist in the absence or the presence of a surmountable or insurmountable antagonist. (B) At similar concentrations, a partial agonist produces a lower response than does a full agonist. (C) Response pattern observed during

simultaneous treatment with a single concentration of a full agonist and increasing concentration of a partial agonist. (D) When an appreciable level of activation of a receptor exists in the absence of an agonist (constitutive activation), the presence of an inverse agonist decreases the degree of receptor activation. *M,* mol/L. (A, Modified from Brunton LL, Lazo JS, Parker KL. Goodman & Gilman's the Pharmacological Basis of Therapeutics. 11th ed. New York: McGraw-Hill; 2006. B and C, Modified from Katzung BG, Masters SB, Trevor AJ. Basic & Clinical Pharmacology. 11th ed. New York: McGraw-Hill; 2009. D, From Rang HP, Dale MM, Ritter JM, et al. Rang and Dale's Pharmacology. 7th ed. Philadelphia: Churchill Livingstone; 2012.)

In addition to the agonist binding site to which antagonists bind, receptor proteins possess many other (allosteric) binding sites through which drugs can influence receptor function by increasing (allosteric facilitators) or decreasing (allosteric antagonists) the affinity of agonists for their binding site, or by modifying efficacy. The resulting effect may be to alter the slope and maximum of the agonist concentration-effect curve.[9] An example of allosteric facilitation includes the activation of benzodiazepines on $GABA_A$ receptors.

The duration of action of an *insurmountable* antagonist depends mostly on synthesis of new receptors, which can take several days. This may have clinically important consequences. For example, phenoxybenzamine, an *insurmountable* α-adrenergic receptor antagonist sometimes used in stage I Norwood procedures to balance the pulmonary and systemic circulations, can produce symptomatic hypotension in some patients. The attenuation or reversal of the decrease in systemic vascular resistance it produces may not be achieved with an α-adrenergic receptor agonist such as dopamine (high dose) or norepinephrine, depending on the dose of phenoxybenzamine given. In such circumstances, the use of a pressor agent that does not act through the α-adrenergic receptor such as vasopressin, which binds on V_1 receptors of smooth muscle cells, must be considered.[10]

Partial agonists are ligands that bind to the same receptor as full agonists but have less intrinsic capacity to produce a response as strong as full agonists, despite full receptor occupancy (Fig. 125.3B). The exact mechanism that accounts for the blunted maximal response seen with partial agonists is unknown. Simultaneous administration of a partial agonist and a full agonist prevents the maximal response usually observed with the full agonist alone because partial agonists have the ability to occupy the receptor population (Fig. 125.3C). Consider what would happen to the maximum effect (Emax) of an agonist in the presence of increasing concentrations of a partial agonist. As the number of receptors occupied by the partial agonist increases, the Emax would decrease until it reached the Emax of the partial agonist. This potential of partial agonists to act both agonistically and antagonistically may be therapeutically exploited. For example, aripiprazole, an atypical neuroleptic agent, is a partial agonist at selected dopamine receptors. Dopaminergic pathways that were overactive would tend to be inhibited by the partial agonist, whereas pathways that were underactive may be stimulated. This might explain the ability of aripiprazole to improve many of the symptoms of schizophrenia, with a small risk of causing extrapyramidal adverse effects. Finally, inverse agonists are ligands that reduce the level of constitutive activation encountered in some receptor systems (Fig. 125.3D).[11]

Receptors play a central role in determining the nature of the pharmacologic effects a drug produces. First, receptors bind with only one or a limited number of structurally related ligands, thus ensuring that the final effect seen in a normal setting occurs only in response to defined stimuli. Second, for a given dose or concentration of a drug, both that drug's affinity to bind to the receptor and the total number of available receptors directly influence the maximal effect a drug can produce. Third, drugs differ in their intrinsic activity in regard to their receptors (eg, partial agonist versus full agonist). Thus the magnitude of the response to any drug is proportional to both the extent of receptor occupancy and the intrinsic activity of the receptor itself, resulting in different dose or concentration relationships for different agonists.

Ion Channels

Ion channels are molecular machines that serve as principal integrating and regulatory devices for the control of cellular excitability. Different types of ion channels have been described: channels responding to electrical (voltage-dependent ion channels), mechanical, or chemical (ligand-gated ion channels) stimuli; ion channels controlled by phosphorylation/dephosphorylation mechanisms; and G protein–gated ion channels. Most ion channels are of the voltage-dependent type and consist mainly of Na^+, K^+, and Ca^{2+} channels. Drugs can affect ion channel function directly by binding to the channel protein and altering its function or indirectly through G proteins and other intermediates. Lidocaine is a good example of a drug that directly affects voltage-gated Na^+ channels by blocking the channel and thus Na^+ entry into the cell. Channel-linked receptors (ligand-gated ion channels) are discussed later.

Enzymes

Enzymes are a specialized class of proteins responsible for catalyzing chemical reactions within the cell and thus are ideal drug targets. Most drugs that alter enzymes activity are substrate analogs of enzymes that inhibit their activity either reversibly (eg, angiotensin-converting enzyme inhibitors acting on peptidyl dipeptidase) or irreversibly (eg, acetylsalicylic acid acting on cyclooxygenase). Drugs may also prevent the normal functioning of enzymes. Fluorouracil, an anticancer drug, is a good example of such drug; it is converted into an abnormal nucleotide that inhibits thymidylate synthetase, thus blocking DNA synthesis.

Carrier Proteins

Several biological elements, such as ions and small organic molecules, are not lipid soluble enough to cross membranes and require a carrier protein (an ion pump or a membrane transporter) to do so.[12] Some carrier proteins use the energy of ATP hydrolysis to move ions or small molecules across a membrane against a chemical concentration gradient or an electrical potential (primary active transport) (Fig. 125.4). These include ion pumps (or ATPases), which transport ions only, and the ATP-binding cassette (ABC) transporters, which catalyze transmembrane movements of various organic compounds including amphipathic lipids and drugs.

Other carrier proteins such as transporters from the solute carrier (SLC) superfamily use energy derived secondarily from the electrochemical potential generated by the concentration gradient of sodium or potassium under the control of the Na^+/K^+-ATPase pump itself coupled with ATP hydrolysis (secondary active transport) (see Fig. 125.4). In such instances, the transport of organic molecules is usually coupled to the transport of H^+ or Na^+, either in the same direction (symport) or in the opposite direction (antiport). The SLC membrane transporters include more than 380 members organized into 52 families. Solute carrier transporters facilitate the transport of a wide array of substrates across biological membranes and have important roles in physiologic processes ranging from the cellular uptake of nutrients to the absorption of drugs and other xenobiotics. The Na^+/H^+ exchanger (NHE), Na^+/Ca^{2+} exchanger (NCX), and $Na^+/K^+/Cl^-$cotransporters (KKCC) belong to this superfamily.

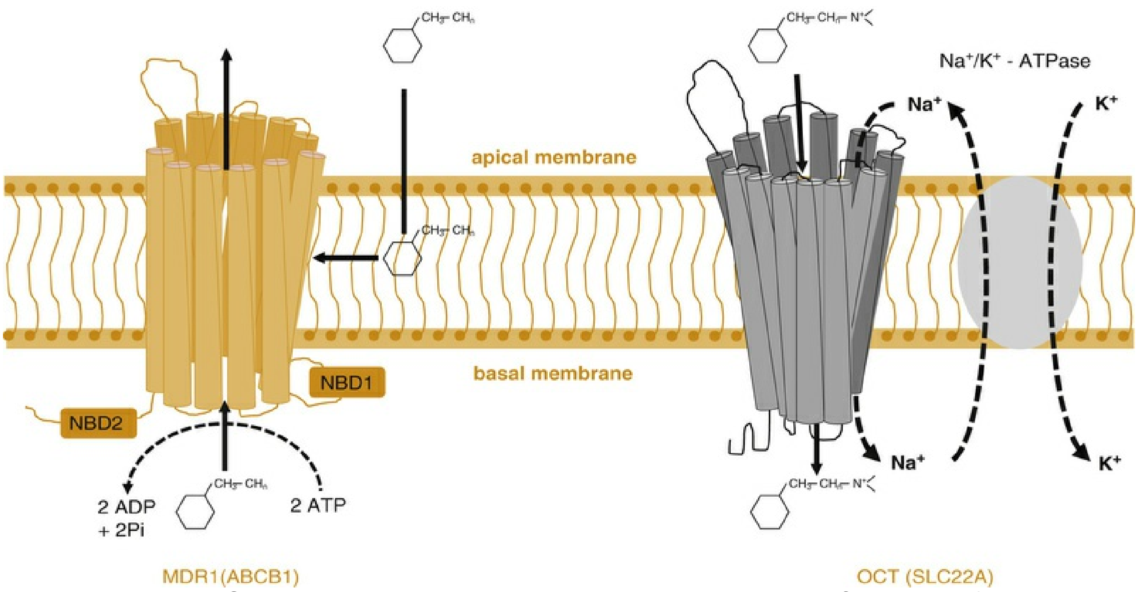

FIG. 125.4 Structure and underlying transport mechanism of the MDR1 transporter (or P-glycoprotein) and of the OTC transporter. The MDR1 transporter uses the energy of ATP hydrolysis to facilitate the efflux of drugs out of the cells (primary active transport). The OTC transporter uses energy derived secondarily from the electrochemical potential generated by the concentration gradient of sodium under the control of the Na^+/K^+-ATPase pump itself coupled with ATP hydrolysis (*secondary active transport*). (Modified from Du Souich P. Transporteurs membranaires. In: Précis de Pharmacologie. Beaulieur P, PIchette V, Desroches J, Du Souich P, eds. Montreal. PUM; 2015.)

The carrier proteins embody a recognition site that makes them specific for a particular permeating species; these recognition sites can also be targets for drugs whose effect is to block the transport system (see Fig. 125.2).[9] Indeed, some drugs bind to these carrier proteins and interfere with the transport system. Digoxin is a typical example of drugs that produce their effect by blockade of an ion pump (the Na^+/K^+-ATPase pump), while furosemide is a typical example of drugs that block a membrane transporter (the $Na^+/K^+/Cl^-$cotransporter [NKCC2]).

Transporters are not only potential drug targets but they play an important role in allowing drugs to reach their site of action in specific organs and tissues. Indeed, to

reach its target, a drug may have to cross several membranes. For example, a drug that is active in the brain needs first to cross intestinal epithelial cells and then the blood-brain barrier. The majority of drugs cross cell membranes using an active transport mechanism, either primary or secondary (as discussed previously), that is under the control of membrane transporters. Membrane transporters are widely expressed throughout the body, most notably in the epithelia of major organs, such as the liver, intestine, kidney, and organs with barrier functions, such as the brain, testes, and placenta.

Several membrane transporters have been discovered. The ABC and the SLC superfamilies are the two main types of membrane transporters involved in drug transport. The ABC superfamily has more than 50 members distributed in different families with those mainly involved in the transport of drugs consisting of the multidrug resistance (MDR) family, the multidrug resistance protein (MRP) family, the breast cancer resistance protein (BCRP), and the bile-salt export protein (BSEP).[13] The main function of these ABC transporters is to facilitate the efflux of drugs from the cells through apical and basal membranes. P-glycoprotein (P-gP) or MDR1, the most extensively studied ABC transporter, is widely distributed with a broad substrate specificity (eg, tacrolimus, digoxin, dexamethasone, chemotherapeutic agents [etoposide, doxorubicin, vinblastine], protease inhibitors) and is subject to drug interactions through inhibition or induction. It limits intestinal drug absorption, participates in drug elimination (liver and kidney), and influences drug tissue distribution (eg, it limits drug entry into the brain). Some cancer cells also express large amounts of P-gP, rendering these cancers multidrug resistant.

Membrane transporters of the SLC superfamily mainly involved in the transport of drugs consist of organic anion transporting polypeptide (OATP), organic cation transporter (OCT), organic cation transporters novel (OCTN), organic anion transporter (OAT), organic anion/urate transporter (URAT), multidrug and toxin extrusion protein (MATE), heteromeric organic solute transporter (OST), peptide transporter (PEPT), humane equilibrative nucleoside transporter (hENT), Na^+-dependent taurocholate co-transporting polypeptide (NTCP), and monocarboxylate transporters (MCT). The main function of the SLC family is to facilitate the entry and the elimination of drugs from the cells through apical and basal membranes.[14]

Receptor Type and Regulation

Four families of receptors, three cell surface receptor types and one nuclear receptor, have been described (Fig. 125.5). Most transmembrane signaling is accomplished by only a few molecular mechanisms, each of which has been adapted to transduce many different signals. These protein families include cell surface receptors and receptors within the cell as well as enzymes and other components that generate, amplify, coordinate, and terminate post receptor signaling.

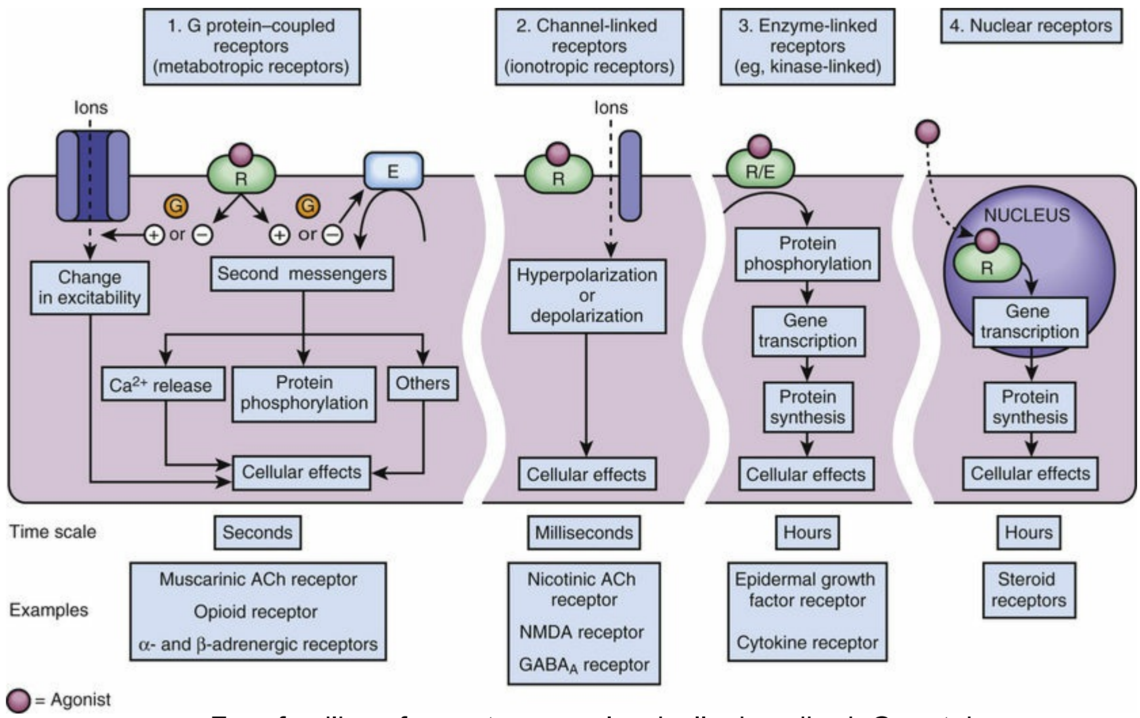

FIG. 125.5 Four families of receptors are classically described: G protein–coupled receptors, channel-linked receptors, enzyme-linked receptors, and nuclear receptors. *ACh,* acetylcholine; *E,* enzyme; *G,* G protein; *GABA,* γ-aminobutyric acid; *NMDA, N*-methyl-D-aspartate; *R,* receptor. (Modified from Rang HP, Dale MM, Ritter JM, et al. Rang and Dale's Pharmacology. 7th ed. Philadelphia: Churchill Livingstone; 2012.)

G Protein–Coupled Receptors

In 1994 Alfred G. Gilman and Martin Rodbell were awarded the Nobel Prize in physiology or medicine for their discovery of G proteins and their role in signal transduction in cells.[15] Furthermore, in 2012 Robert Lefkowitz and Brian Kobilka were awarded the Nobel Prize for chemistry for their discoveries that reveal the inner workings of the β-adrenergic receptor, which led to the seminal discovery that all G protein–coupled receptors (GPCRs) have a similar molecular structure.[16] G proteins are a superfamily of propeller proteins that allow the transduction between the activated receptor (by an agonist) and different intracellular effectors such as enzymes or ion channels, relaying signals from more than 1000 receptors.[17] GPCRs, also known as *metabotropic receptors,* are in fact the first component of the cellular amplification cascade (Fig. 125.6). Indeed, the activation of target enzymes through GPCRs leads to the synthesis of numerous second messengers, which in turn activate other enzymes. The intervention of the second messenger system allows for the diversity of the cellular targets (discussed later). GPCRs are complex signaling machines that participate in most physiologic and pathophysiologic processes and represent the target, directly or indirectly, of approximately 40% of all current therapeutic agents.[18] Of note, pharmacologic agents have been developed for approximately only 10% of GPCRs so far.

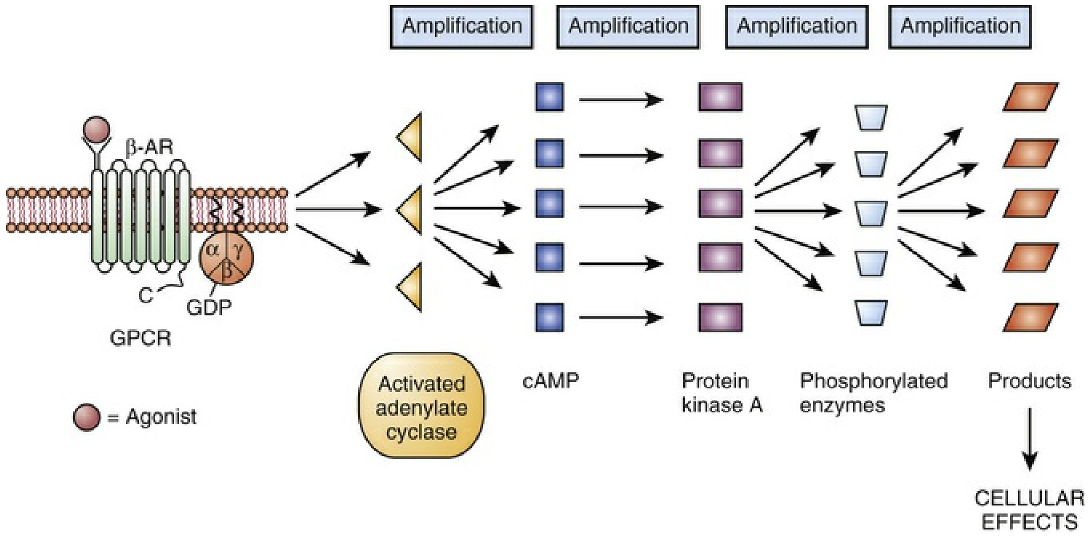

FIG. 125.6 Cellular amplification cascade. After binding to a G protein–coupled receptor (*GPCR*), a ligand (agonist) activates a target enzyme (adenylate cyclase), which synthesizes a second messenger (*cAMP*). The latter then activates other enzymes (protein kinases) that phosphorylate proteins and mediate specific cellular effects. *β-AR*, β-adrenergic receptor; *GDP*, guanosine diphosphate.

Three major families of GPCRs are defined based on their amino acid sequence: Family 1, the largest one, includes receptors for rhodopsin, monoamines (such as β-adrenergic receptors), neuropeptides, opioids, and chemokines. Family 2 consists mainly of receptors for peptides with a large molecular weight, such as calcitonin and secretin. Family 3 has, among others, receptors for glutamate (metabotropic), γ-aminobutyric acid$_B$ (GABA$_B$), and extracellular calcium. Despite these differences, the families of GPCRs share characteristic structural and functional features. All GPCRs share a common serpentine structure consisting of seven transmembrane domains with three extracellular and three intracellular loops. The extracellular regions are involved in ligand binding, and the intracellular regions are primarily involved in signaling.[19] The latter are coupled to a heterotrimeric guanine-nucleotide–binding regulatory protein (G protein) located on the cytoplasmic portion of the cell membrane and are made of three subunits. Each G protein is composed of an α-subunit that is loosely bound to a tightly associated dimer made up of β- and γ-subunits. The activity of a trimeric G protein is regulated by the binding and hydrolysis of guanosine triphosphate (GTP) by the α-subunit (Fig. 125.7).

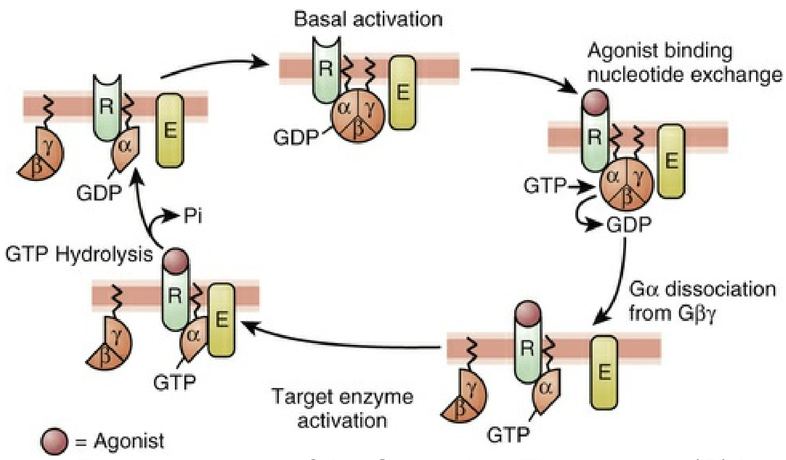

FIG. 125.7 Functional cycle of the G proteins. The receptor (*R*) becomes activated after binding of an agonist. Guanosine diphosphate (*GDP*) bound to the G protein is replaced by guanosine triphosphate (*GTP*), and the α-subunit of the G protein dissociates from the βγ-subunit complex. The α-subunit/GTP complex binds to the target enzyme (*E*) or ion channel, whereas the βγ-subunit complex stimulates several other downstream effectors. The GTPase activity of the α-subunit is increased when the target enzyme or ion channel is bound, leading to hydrolysis of the bound GTP to GDP, whereupon the α-subunit reunites with βγ-subunit complex and the agonist dissociates from the receptor.

Each of the three subunits is encoded by a separate gene selected from more than 20 α, six β, and 12 γ genes, respectively. The α-subunit is essential in the "receptor-effector" coupling. Various α-subunits define different G protein trimers (G_s = stimulatory G protein, G_i = inhibitory G protein, G_o = other G protein, etc.), each of which regulates a distinctive set of downstream signaling pathways. Table 125.2 shows some examples of GPCRs with their trimeric G protein along with their target enzymes or ion channels and second messengers. Some receptors act by way of more than one type of G protein trimer (eg, μ opioid receptor). Approximately 50% of the GPCRs couple to G_i/G_o proteins, approximately 25% couple to G_s, and about the same amount couple to G_q proteins.[20] G_s proteins (made of α_s-subunits) can activate adenylate cyclase and are inhibited by the cholera toxin. In contrast, G_i proteins (made of α_i-subunits) can inhibit adenylate cyclase and open K^+ channels and are inhibited by the pertussis toxin.

TABLE 125.2

Examples of G Protein–Coupled Receptors With Their Trimeric G Protein, Target Enzyme, or Ion Channel, and Second Messengers

GPCR	G Protein	Target Enzyme/Ion Channel	Second Messengers
β_1- and β_2-adrenergic D_1 H_2 V_2	G_s	↑ Adenylate cyclase	↑ cAMP
α_2-adrenergic $M_{2,4}$ μ Opioid AT_1	G_i	↓ Adenylate cyclase	↓ cAMP
α_1-adrenergic	$G_{q/11}$	↑ Phospholipase C	↑ IP_3, DAG, $[Ca^{2+}]_i$

$M_{1,3,5}$ $ET_{A,B}$ AT_1 H_1 V_1			
μ Opioid	$G_{i/o}$	Opens K^+ channels	
μ Opioid	G_o	Closes voltage-dependent Ca^{2+} channels	↓ $[Ca^{2+}]_i$

AT, angiotensin; *cAMP*, cyclic adenosine monophosphate; *D*, dopaminergic; *DAG*, diacylglycerol; *ET*, endothelin; G_i, inhibitory G protein; G_o, other G proteins; *GPCR*, G protein–coupled receptor, G_s, stimulatory G protein; *H*, histamine; *IP3*, inositol 1,4,5-triphosphate; *M*, muscarinic; *V*, vasopressin.

Small G proteins are monomeric G proteins with molecular weight of 20 to 40 kDa. As with heterotrimeric G proteins, their activity depends on the binding of GTP. More than 100 small G proteins have been identified. They are classified into different families: Ras, Rho, Rab, Rap, Ran, and ARF. They are ubiquitous and play key roles in numerous cellular functions such as cell division, proliferation, differentiation, vesicle trafficking, cytoskeletal reorganization, and gene expression.[21]

Channel-Linked Receptors

Also known as *ligand-gated ion channels* or *ionotropic receptors,* channel-linked receptors mediate fast responses, affecting ion fluxes and membrane potential. These receptors possess four distinct characteristics: (1) activation by an agonist or inactivation by an antagonist; (2) flux of ions across a central pore; (3) ion selectivity; and (4) fluctuation among open, closed, and inactivated states. Broadly speaking, two types have been identified: receptors of excitatory mediators and receptors of inhibitory mediators.

Receptors of excitatory mediators (glutamate, aspartate, and acetylcholine), which comprise the *N*-methyl-D-aspartate [NMDA] (Fig. 125.8A) and the nicotinic acetylcholine receptors, are receptors whose activation provokes depolarization of the cell, leading to propagation of the action potential and ultimately secretion of a neuromediator and muscular contraction, for example. These receptors are permeable to monovalent and divalent cations, mainly Na^+, K^+, Ca^{2+}, and magnesium (Mg^{2+}). Ketamine, a dissociative anesthetic, is a noncompetitive NMDA receptor antagonist that prevents the opening of ion channels by glutamate. In addition, the potential neuroprotective effects of ketamine appear to be mediated via NMDA receptor blockade.

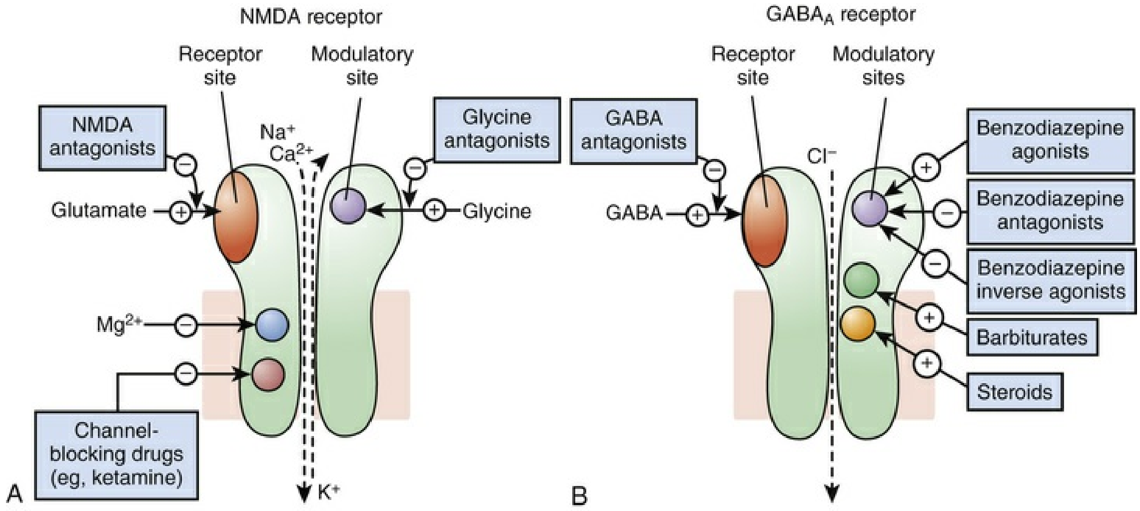

FIG. 125.8 Two important members of the channel-linked receptors, the NMDA receptor (A) and the $GABA_A$ receptor (B). The main sites of drug action on these receptors are shown. *GABA*, γ-aminobutyric acid; *NMDA*, *N*-methyl-D-aspartate.

Receptors of inhibitory mediators, the activation of which provokes hyperpolarization of the cell and therefore decreases cellular excitability, are a group that includes $GABA_A$ (Fig. 125.8B) and glycine receptors. These ligand-gated ion channels are selective for anions such as chloride (Cl^-) or phosphorus (PO_4^{3-}). GABA is the major inhibitory neurotransmitter in the central nervous system, and drugs that potentiate GABAergic inhibition in the brain, such as benzodiazepines and barbiturates, result in sedation and hypnosis.[7] Benzodiazepine agonists enhance Cl^- ion conductance induced by GABA by increasing the frequency of channel-opening events, whereas barbiturates seem to do so by increasing the duration of the GABA-gated channel openings. Both classes of agents bind to sites on the $GABA_A$ molecule that are different from each other and also from the GABA receptor site.

Enzyme-Linked Receptors

Enzyme-linked receptors have an extracellular ligand-binding domain linked to an intracellular domain that possesses an intrinsic catalytic activity. This large and heterogeneous group of membrane receptors can be divided into four subfamilies according to their catalytic activity (tyrosine kinase, guanylate cyclase, tyrosine phosphatase, and serine/threonine kinase). Cytosolic enzymes presenting an activity similar to that of enzyme-linked receptors are also considered to belong to this family of receptors (eg, soluble guanylate cyclase receptors activated by nitric oxide [NO]).

Tyrosine kinase receptors include receptors for neurotrophin,[22] growth factors (epidermal growth factor [EGF], platelet-derived growth factor [PDGF]), as well as insulin and many other trophic hormones. These receptors shift from an inactive monomeric state to an active dimeric state upon agonist binding (dimerization). This is followed by autophosphorylation of the intracellular domain of each receptor and binding of SH2-domain proteins that are themselves phosphorylated. Depending on the receptor subtype, SH2-domain proteins allow the phosphorylated receptor to activate other functional proteins, which eventually results in stimulation of gene

transcription, or are enzymes such as phospholipases, leading to the formation of second messengers (discussed later). One important pathway involved in the transduction mechanisms of tyrosine kinase receptors includes the Ras/Raf/MAP kinase pathway, which is important in cell division, growth, and differentiation (Fig. 125.9).

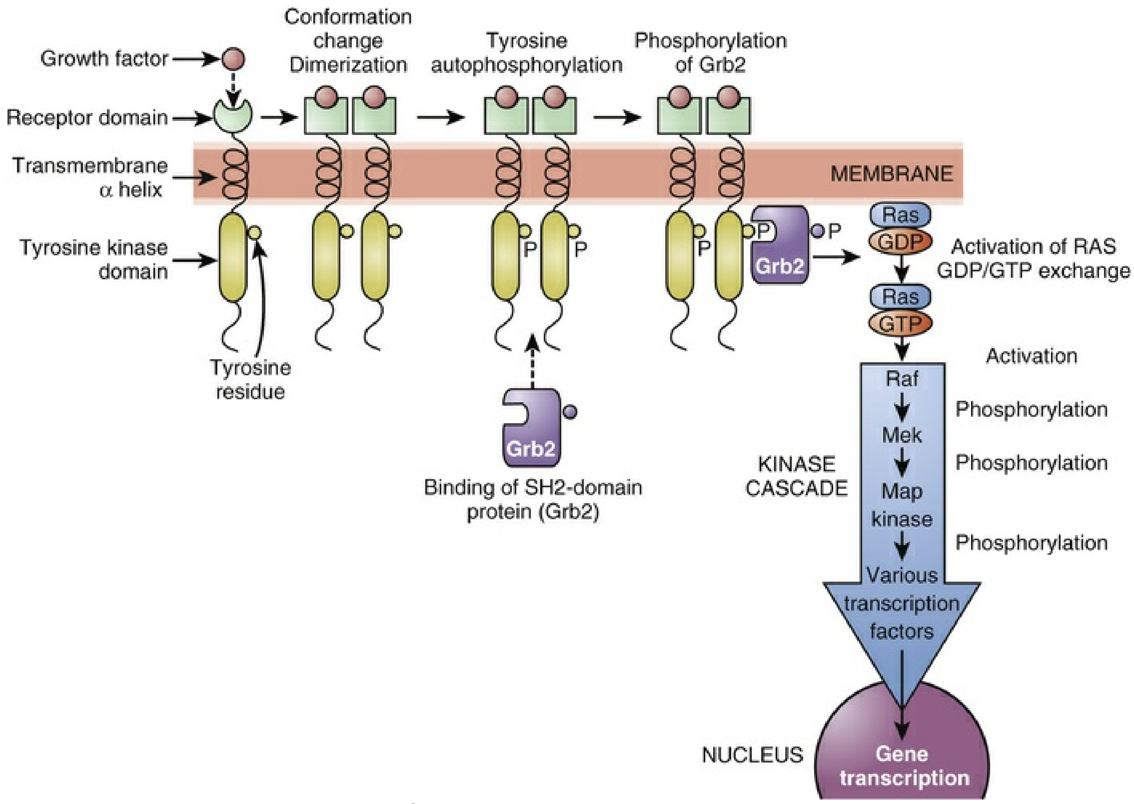

FIG. 125.9 Functioning of kinase-linked receptors. The main steps are dimerization of the receptor, autophosphorylation, and phosphorylation of targeted proteins. The growth factor pathway is shown with the kinase cascade involving the successive phosphorylation of many enzymes (Raf, Mek, Map kinase), eventually leading to gene transcription. *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate. (Modified from Rang HP, Dale MM, Ritter JM, et al. Rang and Dale's Pharmacology. 7th ed. Philadelphia: Churchill Livingstone; 2012.)

Unlike tyrosine kinase receptors, cytokine receptors do not usually possess intrinsic kinase activity; instead, they associate with cytosolic Janus kinases (JAKs). After dimerization of the receptors, which occurs after binding of the cytokine, JAKs phosphorylate tyrosine residues on the receptor, which then result in the binding of another set of proteins called *signal transducers and activators of transcription* (STATs). The bound STATs are themselves then phosphorylated by the JAKs and dimerize and dissociate to migrate in the nucleus and activate gene expression to regulate diverse biological processes controlling the synthesis and release of many inflammatory mediators, growth, development, and homeostasis.

Guanylate cyclase–linked receptors are unique because they synthesize their own second messengers upon agonist binding. The natriuretic peptide receptors, including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) receptors, belong to this family (Fig. 125.10). The

extracellular NH_2-terminal constitutes the binding domain. There is a short transmembrane segment whose role is to anchor the receptor protein to the membrane. The intracellular domain is made of two different entities: (1) a protein kinase homology domain whose function is to control and relay receptor activation to the catalytic domain and (2) a guanylate cyclase catalytic domain, also known as *particulate guanylate cyclase,* involved in the synthesis of cyclic guanosine monophosphate (cGMP) from GTP.[23] In addition to this particulate guanylate cyclase (the membrane form of the enzyme), an intracellular soluble form exists. It is a heterodimer consisting of α- and β-subunits, both of which are necessary for enzyme activity, and is expressed in most tissues, though not uniformly.[24] It is activated by intermediate substances derived from the biosynthesis of eicosanoids (prostaglandins and leukotrienes) and by NO and NO donors such as sodium nitroprusside and nitroglycerin (discussed later). Guanylate cyclases and cGMP-mediated signaling cascades play a central role in the regulation of diverse pathophysiologic processes, including vascular smooth muscle motility, intestinal fluid and electrolyte homeostasis, and retinal photo transduction.[25]

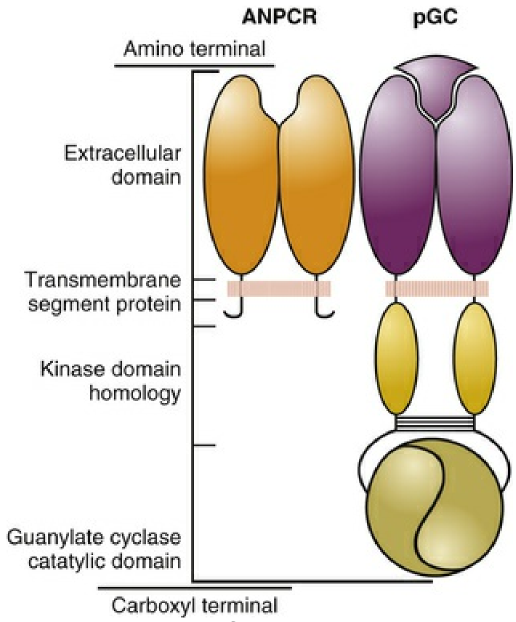

FIG. 125.10 Molecular structure of the natriuretic peptide receptors. *Left,* Atrial natriuretic peptide–C receptor (*ANPCR*) is a clearance receptor that does not possess the kinase and guanylate cyclase domains. It plays a role in the catabolism of natriuretic peptides. *Right,* Typical particulate guanylate cyclase receptor (*pGC*) (ANP-A or -B receptor) is shown with its extracellular dimeric protein-binding domain. The intracellular domain consists of a protein kinase homology domain and a guanylate cyclase catalytic domain.

Nuclear Receptors

Nuclear receptors belong to a family of functionally and structurally related proteins. They regulate gene expression and are not associated with a membrane. Their principal mechanism of action is shown in Fig. 125.11. The agonist, which must

be lipid soluble, diffuses into the cell and binds to the nuclear receptor located either in the cytosol or in the nucleus. The complex agonist-activated receptor then binds on high-affinity sites on DNA, hormone response element (HRE), situated on the promoter region of genes, whose transcription can then be induced or suppressed. Because gene transcription is at their origin, these effects are slow to develop.

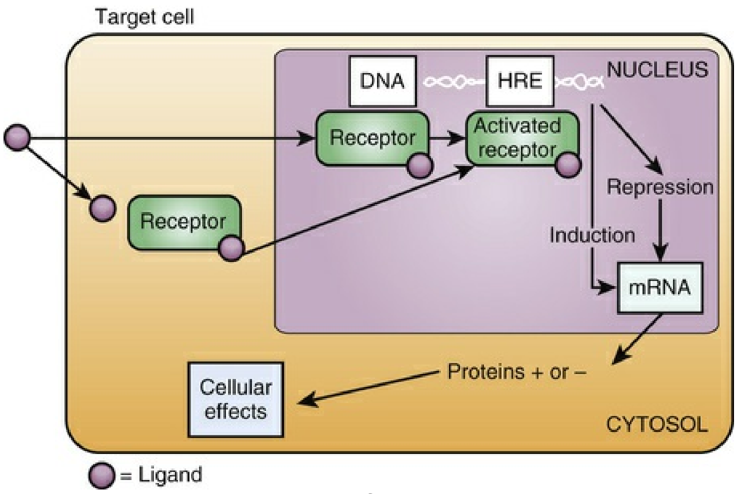

FIG. 125.11 Activation and action of nuclear receptors, located either in the cytosol (eg, steroid receptors) or in the nucleus (eg, vitamin D receptor). *DNA*, deoxyribonucleic acid; *HRE*, hormone response element.

Endogenous agonists for these receptors include steroid and thyroid hormones as well as agents such as retinoic acid and vitamin D. The most commonly used drugs that target these receptors include exogenous steroids and lipid-lowering agents. For many of theses receptors, the corresponding hormone or vitamin has not been identified; these receptors are therefore referred to as *orphan nuclear receptors.*

Receptor Regulation

Continued exposure of a receptor to an agonist often results in a progressive loss of receptor responsiveness, with a diminished receptor-mediated response over time. This is called *desensitization* (or tachyphylaxis) and is classified into two forms. Homologous desensitization is a process in which only the activated receptor is "turned off" or desensitized, whereas heterologous (cross-) desensitization refers to processes in which the activation of one type of receptor can result in the desensitization of other types of receptors. Interaction of the receptor with an antagonist prevents the occurrence of desensitization.

In general, desensitization occurs in three ways (Fig. 125.12A): (1) inactivation or uncoupling of the receptor, which is usually the result of receptor phosphorylation and occurs within seconds to minutes of agonist exposure; (2) sequestration of the receptor in endosomes (from there the receptor is recycled to the cell membrane); and (3) down-regulation, which is characterized by receptor endocytosis and destruction in lysosomes with a net loss of receptors in the cell (at the cell membrane and within the cell). The latter develops more slowly than uncoupling, taking hours to days.[26] In addition to receptor degradation, decreased synthesis of the receptor also contributes to this process. Downregulation is responsible for the decreased

responsiveness to prolonged exogenous catecholamine infusion frequently seen in the critical care population.[27] Desensitization is usually reversible, within minutes (inactivation) to hours (sequestration/down-regulation) of removal of the agonist depending on the specific receptor and cell type, the concentration of the agonist, and the duration of the exposure to the agonist.

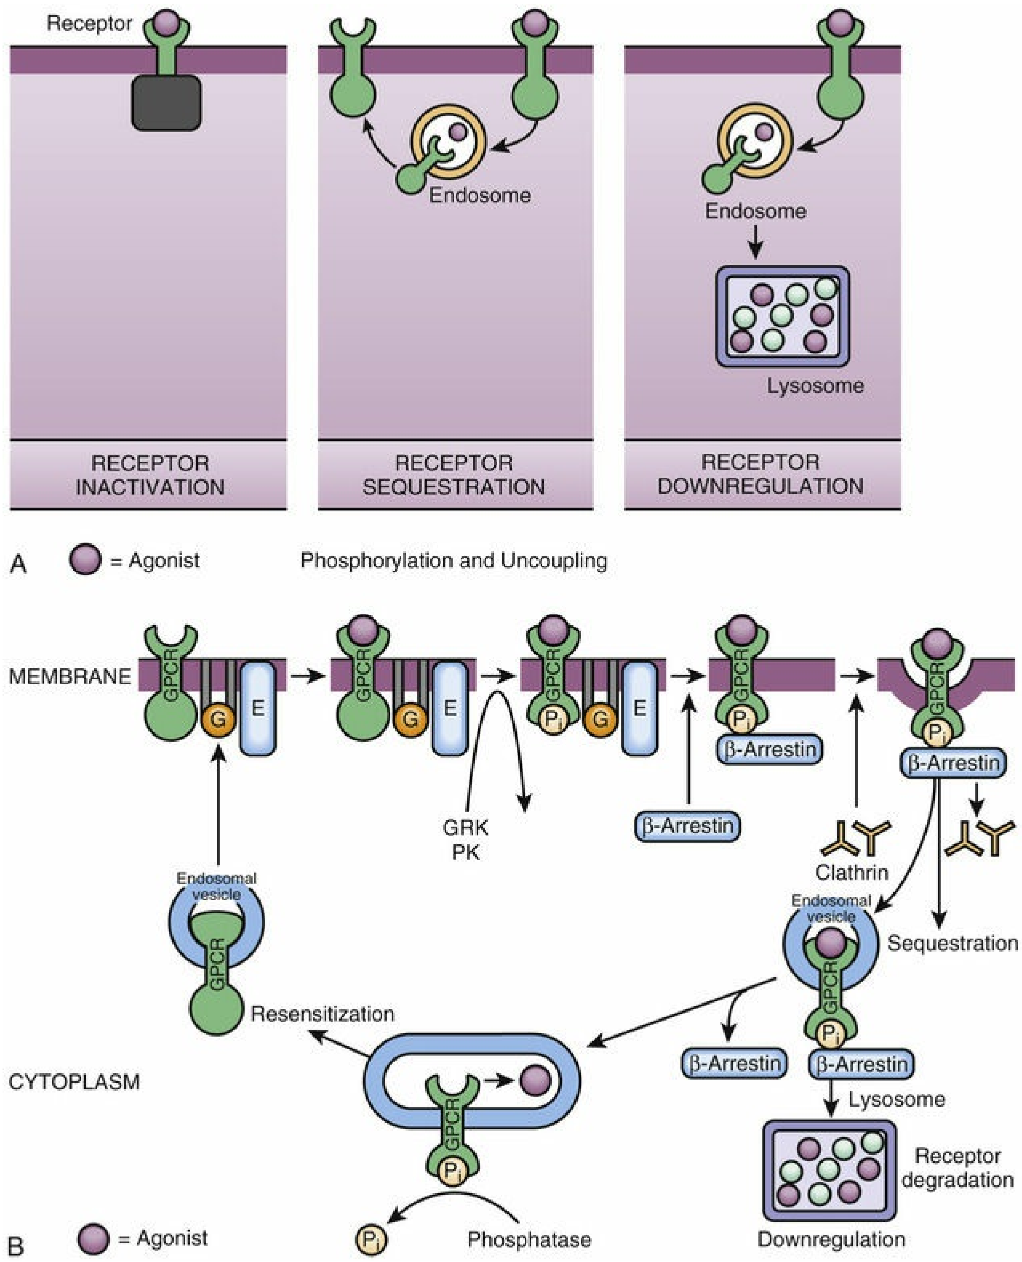

FIG. 125.12 Desensitization in response to an agonist. (A) Ways in which receptors can become desensitized to an agonist. (B) Homologous desensitization of GPCR. *E,* G protein effectors; *G,* G protein; *GPCR,* G protein–coupled receptor; *GRK,* G protein–coupled receptor kinase; *PK,* second-messenger–dependent protein kinases. (A, Modified from Alberts B, Johnson A, Lewis J, et al. Molecular Biology of the Cell. 4th ed. London: Garland Science; 2002. B, Modified from Luttrell LM, Lefkowitz RJ. The role of beta-arrestins in the termination and transduction of G-protein-coupled receptor signals. J Cell Sci. 2002;115;455-465.)

Homologous desensitization of GPCRs results from these three distinct and coordinated processes (Fig. 125.12B).[28] It begins within seconds of exposure to the agonist and is initiated by phosphorylation of the receptor by G protein–coupled receptor kinases (GRKs) and second messenger–dependent protein kinases (protein kinase A [PKA] and protein kinase C [PKC]). Once phosphorylated, the receptor binds with high affinity to members of the arrestin gene family, the β-arrestins. The β-arrestin binding prevents the receptor–G protein interaction, leading to termination of signaling by G protein effectors (receptor inactivation or uncoupling). The receptor-bound β-arrestin can also act as an adapter protein to couple the receptor to clathrin-coated pits, inducing receptor-mediated endocytosis or sequestration. Subsequently, the receptor is either recycled to the cell membrane or degraded (receptor downregulation). Resensitization of a GPCR requires its dephosphorylation and dissociation from its agonist. In contrast to homologous desensitization, heterologous desensitization of GPCRs occurs when inhibition of one GPCR is induced by the activation of another GPCR. One well-recognized mechanism is the phosphorylation of one GPCR by second messenger–dependent protein kinases (PKA and PKC) activated by any other GPCRs. Such phosphorylation of the receptor impairs receptor–G protein coupling and leads to the inactivation of the receptor. However, it is becoming increasingly clear that receptor phosphorylation is not the exclusive mediator of heterologous desensitization and that events downstream are involved.[29]

As GPCRs, channel-linked and enzyme-linked receptors are desensitized following prolonged or repeated agonist exposure. Channel-linked receptors are phosphorylated by second messenger–dependent protein kinases while tyrosine kinase receptors are internalized.

Upregulation refers to the increase in receptor sensitivity seen in the setting of lack of agonist stimulation or prolonged presence of a receptor antagonist. This is best exemplified by a phenomenon seen when a β-adrenergic blocking agent such as propranolol is administered for a long period of time and abruptly discontinued. Because a greater number of sensitized β-adrenergic receptors become available for stimulation by endogenous agonists, rebound hypertension is observed.

Signal Transduction Mechanisms: Intracellular Messengers and Effectors

After binding of an agonist to receptors such as GPCRs or enzyme-linked receptors, the signal transduction mechanisms from the membrane first involve the production of second messengers such as cyclic adenosine monophosphate (cAMP), cGMP, arachidonic acid and its metabolites, diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP_3), and Ca^{2+}. These, in turn, activate protein kinases and calcium-binding proteins, all of which result in different biological effects (Fig. 125.13). Thus the synthesis and degradation of intracellular second messengers are described first, followed by a review of the role of protein kinases and calcium-binding proteins in the transduction mechanisms.

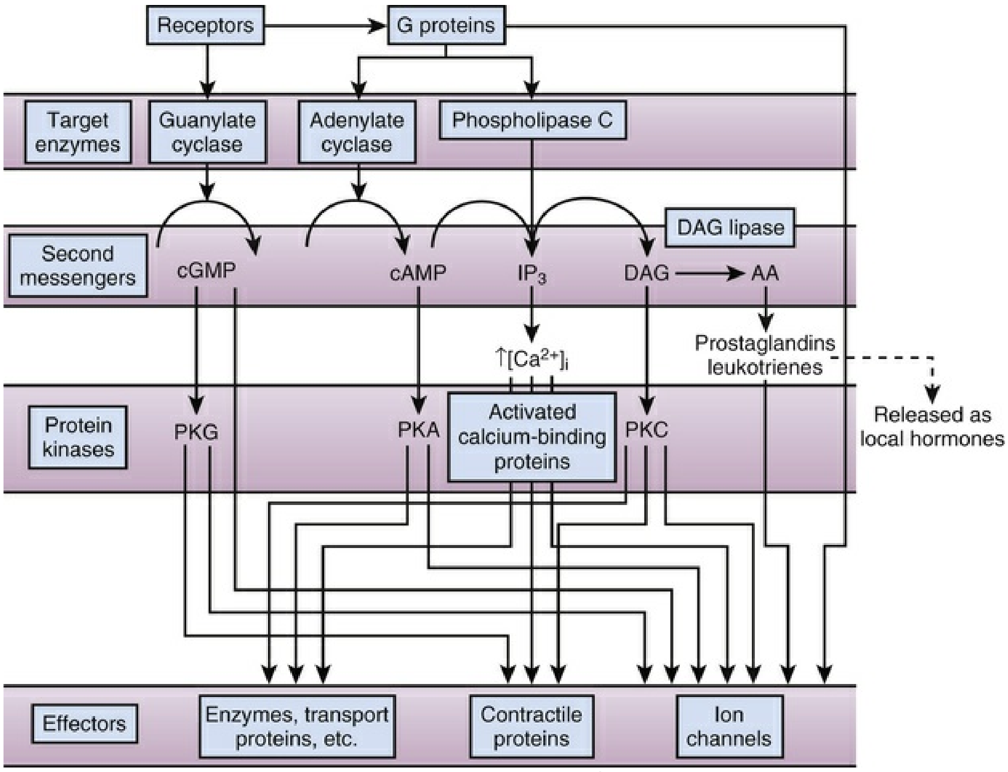

FIG. 125.13 Transduction mechanisms of membrane signaling. *AA*, arachidonic acid; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *DAG*, diacylglycerol; *IP_3*, inositol 1,4,5-triphosphate; *PKA*, protein kinase A; *PKC*, protein kinase C; *PKG*, protein kinase G. (Modified from Rang HP, Dale MM, Ritter JM, et al. Rang and Dale's Pharmacology. 7th ed. Philadelphia: Churchill Livingstone; 2012.)

Second Messengers

Cyclic Adenosine Monophosphate

This pathway is involved in signal transduction initiated by binding of agonists to GPCRs. cAMP is synthesized from adenosine triphosphate (ATP) after the action of adenylate cyclase, which is a transmembrane glycoprotein of the cell membrane. To date, nine forms of adenylate cyclase (types I to IX) have been identified by molecular cloning, and several have described features that are hypothetical.[30] Cyclic AMP regulates many aspects of cellular function (cell division and differentiation, ion transport, etc.) by one common mechanism involving activation of protein kinases. These, in turn, regulate the function of many different cellular proteins by catalyzing the phosphorylation of serine and threonine residues. Phosphorylation can then either activate or inhibit target enzymes or ion channels.[9] As previously mentioned, receptors coupled with G_s proteins stimulate adenylate cyclase and produce an increase in cAMP, whereas receptors coupled with G_i proteins inhibit adenylate cyclase and reduce cAMP.

The degradation of cAMP is catalyzed by phosphodiesterases leading to the production of 5′-AMP, an inactive product. Phosphodiesterases are a complex family of enzymes divided into 11 groups according to mechanism of regulation, selectivity for the substrate (cAMP or cGMP), preferential localization, and sensitivity to

various inhibitors.[31] In critically ill children, milrinone, used for its positive inotropic effect and vasodilating properties, is a phosphodiesterase inhibitor selective for the type III isoenzyme.

Cyclic Guanosine Monophosphate

As discussed previously, guanylate cyclase is part of the cytosolic portion of some transmembrane receptors (membrane form) but also exists as a cytosolic enzyme (soluble form) activated by various molecules, including NO. Stimulation of guanylate cyclase results in the accumulation of cGMP. This second messenger then regulates complex signaling cascades through immediate downstream effectors, including cGMP-dependent protein kinases (eg, protein kinase G [PKG]), cGMP-regulated phosphodiesterases (mainly type II and III), and cyclic nucleotide-gated ion channels (cells of the retina), which eventually leads to a variety of physiologic effects.[32] For example, NO readily passes across the target cell membrane and activates soluble guanylate cyclase in vascular smooth muscle, resulting in increased cGMP production with the regulation of various downstream targets such as protein kinases and ion channels, which culminates in vasodilatation.

As with cAMP, the degradation of cGMP into inactive GMP is catalyzed by phosphodiesterases. In pulmonary and penile vascular smooth muscle cells, phosphodiesterase type V is responsible for the degradation of cGMP; inhibition of this enzyme results in an accumulation of cGMP in the cytosol with smooth muscle relaxation and vasodilatation. As such, phosphodiesterase type V inhibitors (eg, sildenafil) are widely recognized as efficacious for the treatment of erectile dysfunction in men and have been shown to induce pulmonary vasodilatation both in children and adults and are part of the strategies available for the treatment of pulmonary hypertension.[33-35]

Arachidonic Acid and Its Metabolites

Arachidonic acid and its metabolites (prostaglandins and leukotrienes) are now considered intracellular messengers.[36] Arachidonic acid is a component of membrane phospholipids released either in a one-step process, after phospholipase A_2 (PLA_2) action, or a two-step process, after phospholipase C and DAG lipase actions. Arachidonic acid is then metabolized by cyclooxygenase (COX) and 5-lipoxygenase, resulting in the synthesis of prostaglandins and leukotrienes, respectively. These intracellular messengers play an important role in the regulation of signal transduction implicated in pain and inflammatory responses. Corticosteroids inhibit PLA_2 activity, whereas nonsteroidal antiinflammatory drugs inhibit COX activity.

Diacylglycerol and Inositol Triphosphate

Phospholipase C is the target enzyme for some GPCRs (phospholipase C-β) as well as enzyme-linked receptors such as tyrosine kinase receptors (phospholipase C-γ). It splits phosphatidylinositol, a membrane-bound phospholipids, into DAG and IP_3, both of which function as second messengers. The most important function of DAG is to activate the membrane-bound PKC, which catalyzes the phosphorylation of a variety of intracellular proteins. IP_3 binds to and opens an IP_3-gated Ca^{2+} release

channel on the endoplasmic reticulum membrane, which results in an increase in free intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$).

Calcium Ions

$[Ca^{2+}]_i$ is critically important as a regulator of cell function. Indeed, an increase in $[Ca^{2+}]_i$ is the most important intracellular messenger signaling pathway known in biological systems. When $[Ca^{2+}]_i$ is at its baseline value, few proteins have an affinity sufficient to bind to Ca^{2+}. Once membrane signaling occurs, an increase in $[Ca^{2+}]_i$ results, derived from either the extracellular space or from the lumen of the endoplasmic reticulum, and allows binding of proteins to Ca^{2+}. Finally, this binding can trigger contraction, secretion, a modification in metabolism regulation, or several other effects depending on the cell type involved. To maintain a low resting $[Ca^{2+}]_i$, Ca^{2+} is permanently expulsed from the cytosol into the extracellular compartment or into the endoplasmic reticulum via a Ca^{2+}-ATPase and Na^+/Ca^{2+} exchanger.

Phosphorylation of Proteins

Many receptor-mediated signals produce variations in the concentration of second messengers, such as cAMP, cGMP, arachidonic acid, DAG, IP_3, and Ca^{2+}, as previously discussed. These can then modify the activity of other proteins, mainly protein kinases and calcium-binding proteins.

Protein Kinases

Protein kinases are enzymes located in the cytoplasm that phosphorylate proteins. The main protein kinases consist of PKA, PKG, and PKC[37] as well as tyrosyl protein kinases (part of tyrosine kinase receptors). They are distinguished from each other by the different intracellular second messengers involved in their regulation and by the selective substrates they use. They all have a binding site for Mg^{2+}-ATP (phosphate donor) and for substrate protein as well as various regulatory sites. Phosphorylation of these proteins is short lived because protein phosphatases rapidly dephosphorylate proteins previously phosphorylated by protein kinases, thus terminating the intracellular signal.

Calcium-Binding Proteins

Calcium exerts its control in cellular function by virtue of its ability to regulate the activity of many different proteins, such as channels, transporters, and transcription factors. In the majority of cases, a calcium-binding protein serves as an intermediate between Ca^{2+} and the regulated functional protein. Calcium-binding proteins represent a large group of cytosolic proteins and include the calmodulin and annexin (or lipocortin) families.

Multiple Drug Targets Within an Organ System: The Myocardium

This section highlights the molecular mechanisms behind therapeutic agents that

increase contractility and accelerate relaxation within the myocardium. During cardiac excitation-contraction coupling, Ca^{2+} is the essential second messenger (Fig. 125.14).[38] During the depolarization phase of the cardiac action potential, Ca^{2+} enters the cell through voltage-gated L-type Ca^{2+} channels. Ca^{2+} entry triggers Ca^{2+} release from the sarcoplasmic reticulum (SR) through a SR membrane ion channel—the cardiac/isoform 2 ryanodine receptor (RyR2). This process is known as *calcium-induced Ca²+ release* (CICR). The combination of Ca^{2+} influx and CICR raises $[Ca^{2+}]_i$, allowing Ca^{2+} binding to troponin C (TnC), which permits cross-bridging between actin and myosin and ultimately contraction. For relaxation to occur $[Ca^{2+}]_i$ must decline, allowing Ca^{2+} to dissociate from TnC. This requires Ca^{2+} transport out of the cytosol by four pathways: SR Ca^{2+}-ATPase (the main one, also known as SERCA), sarcolemmal Na^+/Ca^{2+} exchanger, sarcolemmal Ca^{2+}-ATPase, and mitochondrial Ca^{2+} uniport. SR Ca^{2+}-ATPase activity is modulated by phospholamban, an endogenous inhibitor. Under physiologic conditions, there is no net gain or loss of cellular Ca^{2+} with each contraction-relaxation cycle.

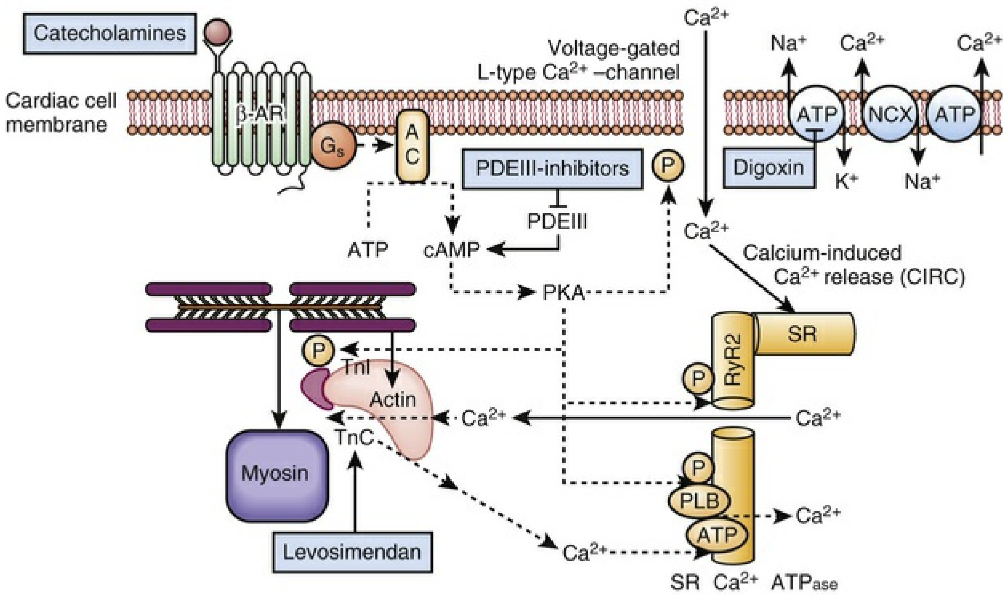

FIG. 125.14 Cardiac excitation-contraction coupling and molecular targets of therapeutic agents with positive inotropic and lusitropic effects. (Note: Under physiologic conditions, NCX works mainly in the Ca^{2+} extrusion mode; however, if intracellular Na^+ concentration is elevated, as is the case with digoxin, it can work in the Ca^{2+} influx mode.) *AC,* adenylate cyclase; *ATP,* adenosine triphosphate; *β-AR,* β-adrenergic receptor; *cAMP,* cyclic adenosine monophosphate; G_s, stimulatory G protein; *NCX,* Na^+/Ca^{2+} exchanger; *P,* phosphorus; *PDE,* phosphodiesterase; *PKA,* protein kinase A; *PLB,* phospholamban; RyR_2, cardiac/isoform 2 ryanodine receptor; *SR,* sarcoplasmic reticulum; *TnI,* troponin I; *TnC,* troponin C. (Modified from Toller GT, Stranz, C. Levosimendan, a new inotropic and vasodilating agent. Anesthesiology. 2006;104:556-569.)

There are two main ways to pharmacologically increase the strength of cardiac contraction (see Fig. 125.14)[38,39]: (1) by increasing the amount of $[Ca^{2+}]_i$ available for binding to TnC or (2) by increasing the sensitivity of myofilaments to Ca^{2+}:

1. *Catecholamines and phosphodiesterase type III inhibitors (PDEIII inhibitors).* β-adrenergic receptor stimulation by catecholamines activates a GTP-binding protein (G_s), which stimulates adenylate cyclase to produce cAMP, whereas PDEIII inhibitors (eg, milrinone) prevent cAMP degradation. The resulting increase in cAMP activates PKA, which, in turn, phosphorylates intracellular targets, including voltage-gated L-type Ca^{2+} channels, RyR2, phospholamban, and troponin I (TnI). Phosphorylation of voltage-gated L-type Ca^{2+} channels enhances Ca^{2+} entry into the cytosol with subsequent increase in CICR from the SR and contraction (positive inotropic effect of catecholamines and PDEIII inhibitors). In contrast, phosphorylation of phospholamban activates SR Ca^{2+}-ATPase with increased Ca^{2+} transport from the cytosol back to the SR and thus promotes relaxation (positive lusitropic effect of catecholamines and PDEIII inhibitors). This action also contributes to the overall gain in cardiac excitation-contraction coupling by increasing the SR Ca^{2+} content available for the next contraction. However, such increased loading of the SR with Ca^{2+} may be a key factor in the development of Ca^{2+}-mediated arrhythmias.[40] The lusitropic effect of catecholamines and PDEIII inhibitors is also mediated by phosphorylation of TnI, which decreases the affinity of myofilaments for Ca^{2+}.

2. *Digoxin.* Digoxin enhances myocardial contractility, although modestly, by inhibiting the Na^+/K^+-ATPase pump with a resultant mild increase in intracellular Na^+. This increase of Na^+ subsequently inhibits the extrusion of Ca^{2+} from the cytosol outside the cell by the sarcolemmal Na^+/Ca^{2+} exchanger. Ca^{2+} not extruded from the cytosol is stored in SR and allows increased release of Ca^{2+} during the next contraction.

3. *Ca^{2+} sensitizers.* More recently, Ca^{2+} sensitizers (eg, levosimendan), a new class of inotropic agents, have been developed. They improve cardiac contractility by binding to TnC and stabilizing its interaction with Ca^{2+}, which results in prolonged interaction of actin-myosin filaments. One possible limitation of some Ca^{2+} sensitizers is worsening diastolic function due to facilitation of cross-bridging at diastolic Ca^{2+} concentrations. However, this does not appear to be the case of levosimendan because its binding to TnC depends on $[Ca^{2+}]_i$ (ie, when $[Ca^{2+}]_i$ increases during systole, it facilitates actin-myosin interaction, and when $[Ca^{2+}]_i$ decreases during diastole, it does not). One potential beneficial effect of theses agents compared with catecholamines and PDEIII inhibitors comes from the fact that they do not increase $[Ca^{2+}]_i$ and, as such, have neutral effects on myocardial oxygen demand and heart rhythm.[39]

Promising new inotropic agents have been developed.[41,42] Among these, istaroxime, a lusi-inotropic agent, inhibits Na^+/K^+-ATPase pump (increased inotropy like digoxin) and stimulates SR Ca^{2+}-ATPase (accelerated relaxation). Cardiac myosin activators (eg, omecamtiv mecarbil) represent a new class of compounds that directly influence the cross-bridge cycle. They promote actin-dependent phosphate release moving the cross-bridge into its strongly bound force-producing state. As a consequence, more cross-bridges are activated per unit of time, and contractile force increases. Although still under investigations in adults, these novel approaches to improving cardiac function provide the hope that such agents may soon be

available.

Drug Response and Genetic Polymorphisms

"The right dose of the right drug to the right person" is one of the goals of pharmacogenomics and personalized medicine. It is estimated that genetic factors can account for 20% to 95% of variability in drug disposition and effects.[43] Although drug response variation is often multifactorial (even more so in critically ill children), genetic polymorphisms occurring in genes that encode drug-metabolizing enzymes, drug targets (eg, receptors, enzymes), drug transporters, or proteins involved in signaling pathways may partially account for therapeutic failure and toxicity.

Most genetic variations involve single-nucleotide polymorphisms (SNPs)—that is, the exchange of a single nucleotide in the DNA sequence. Small insertions and deletions, variable-number tandem repeats, gene deletions, and gene duplications can also take place. Depending on where SNPs occur, they can result in no change in the protein amino acid sequence (silent polymorphism or synonymous SNP) or in a change in the coded amino acid sequence (nonsynonymous SNP) that can have no functional consequence or can result in altered protein function. The latter can have significant clinical or therapeutic implications. In addition, given that genes often present many SNPs, it has become increasingly recognized that single SNPs fail to predict drug responses, whereas combinations of SNPs on a given chromosome (specific haplotype) are clinically more significant and can better determine drug effects.[44]

Genetic Polymorphisms and Drug Disposition

Many major enzymes involved in phase I and phase II drug metabolism have known polymorphisms leading to phenotypic differences (ie, clinically significant alteration in drug-metabolizing enzyme activities).[43] For a specific polymorphic drug metabolizing enzyme, homozygous individuals for the wild-type allele exhibit normal enzymatic activity (extensive metabolizers), heterozygous individuals may have reduced enzymatic activity (heterozygous extensive/intermediate metabolizers), and homozygous individuals with the mutant allele have low enzymatic activity (poor metabolizers). For some enzymes (eg, CYP2D6), individuals have ultrarapid metabolism as a result of gene duplications of functional alleles (ultrarapid metabolizers). The clinical consequences of such polymorphisms may be fourfold: (1) poor metabolizers can have an enhanced drug effect, either therapeutic or toxic, resulting from higher plasma concentrations of a given drug; (2) poor metabolizers can experience a diminished drug effect resulting from the inability of a prodrug to be converted into the active metabolite due to low enzymatic activity; (3) ultrarapid metabolizers can experience diminished drug effect resulting from markedly lower plasma concentrations of a given drug; and (4) ultrarapid metabolizers can experience enhanced drug effect from an excessive conversion of a prodrug into the active metabolite as a result of supranormal enzymatic activity. Codeine is a good example of the clinical impact of CYP2D6 polymorphism. CYP2D6 catalyses the biotransformation of codeine into morphine, the active compound. CYP2D6 poor metabolizers are at increased risk of experiencing inadequate

analgesia as a failure to convert codeine into morphine, whereas CYP2D6 ultrarapid metabolizers may be at increased risk for opioid-related adverse effects as a result of increased formation of morphine from codeine.[45,46]

Genetic Polymorphisms, Drug Targets, and Signaling Mechanisms

Genetic polymorphisms in signaling mechanisms involving GPCRs, transporters, and enzymes have also been identified and can influence drug response.[47-49] Mutations in G proteins have also been shown to cause certain diseases.[50] As an example, there has been considerable progress in cardiovascular pharmacogenetics in adults, where the mainstay of treatment comprises β-blockers, angiotensin-converting enzyme inhibitors, aldosterone antagonists, and diuretics. The most studied genetic variants relating to these pharmacologic interventions are summarized in Table 125.3.[51] However, pharmacogenetics-based heart failure therapy has not reached the bedside due to inconsistent results. As multiple factors beyond genetic variability have the potential to influence drug response (see Fig. 125.1), mathematic models and systems biology capable of integrating all of these factors may have a better chance to adequately predict drug response and eventually be applied clinically.

TABLE 125.3

Summary of Most Studied Genetic Variants in the Pharmacogenetics of Heart Failure

Receptor/Enzyme/Transporter	Genetic Variant	Pharmacogenetic Association
Angiotensin-converting enzyme (ACE)	Insertion/deletion (I/D)[a]	Individuals with the DD genotype have high ACE activity
		Benefits of high-dose ACE inhibitors appear maximal for DD patients
β_1-adrenergic	Arg389Gly	Arg389 associated with a greater agonist-promoted coupling
		Associated with enhanced response to some β-blockers (bucindolol, atenolol, metoprolol) in some studies
		Associated with increased inotropic potency to norepinephrine
β_1-adrenergic	Ser49Gly	Gly49 associated with enhanced desensitization and agonist-promoted downregulation
		Inconsistent evidence that this translates to difference in drug response
β_2-adrenergic	Thr164Ile	Ile164 loss-of-function allele, attenuated response to sympathetic stimulation
β_2-adrenergic	Gln 27Glu[b]	Glu27 associated with complete resistance to downregulation
β_2-adrenergic	Arg16Gly[b]	Arg16 associated with a reduction in agonist promoted downregulation
G protein receptor kinase 5 (GRK5)	Gln41Leu	Leu41 gain-of-function allele with enhanced desensitization
(acts on β_1- and β_2-adrenergic)		Associated with improved survival in patients with heart failure by providing a "genetic β-blockade"
Nitric oxide synthase 3 (NOS3)	Asp298Glu	Glu298 associated with good response to hydralazine/isosorbide dinitrate
Renal sodium transporter	SLC12A3 Ala264	Associated with enhanced excretion potassium and chloride with all loop diuretics

[a]Referring to presence or absence of an insertion at the 287th base-paired insertion.

[b]Gln27Glu and Arg16Gly are in linkage disequilibrium.

Drug Response and Development

From birth through puberty, dramatic developmental changes occur that can have a profound impact on drug disposition and action. Most studies have evaluated the effect of age on pharmacokinetics, revealing clinically important differences compared with adults.[52,53] The ontogenesis of important drug-metabolizing enzymes, the cytochrome P-450 enzymes, is a good example of how development affects drug disposition and how age is an important determinant in selecting appropriate doses (see Table 125.3). Even though developmental changes are also expected to affect the different players involved in pharmacodynamics, scarce data concerning the ontogenesis of specific drug targets, signal transduction mechanisms, and intracellular messengers are currently available. To date, human studies have mainly dealt with receptor expression (and not function), mostly in the brain, and have found age-related differences in terms of receptor density and regions of the brain where receptors are expressed.[54-56] The exact consequences of these differences are unknown, but it is speculated that they may play a role in organ maturation as well as in the pathophysiology of diseases and drug response.

Drug Response and Disease

Although a vast literature exists regarding the effects of diseases on drug pharmacokinetics, limited data are available about pharmacodynamic changes occurring as a consequence of illness. Of particular interest for the critically ill population is the myocardial hyporesponsiveness to catecholamines observed during sepsis. Sepsis, which is associated with elevated circulating catecholamine levels, induces a disruption at various levels of the β-adrenergic signaling cascade (Fig. 125.15).[3] Postulated mechanisms, mainly derived from animal studies, include inactivation of catecholamines by superoxide, decreased β-adrenergic receptor density, decreased stimulatory G proteins (G_s), and increased inhibitory G proteins (G_i) (β_2-adrenergic receptor in rat ventricular cardiomyocytes can couple to G_i; whether human cardiac β-adrenergic receptors can do the same is unknown[57]). These changes result in decreased activity of adenylate cyclase and reduced levels of cAMP. In addition, NO released during sepsis activates soluble guanylate cyclase with increased cGMP and activation of PKG, which in turn inhibits PKA. These alterations ultimately lead to decreased contractility, impaired myocyte relaxation, and reduced chronotropy.

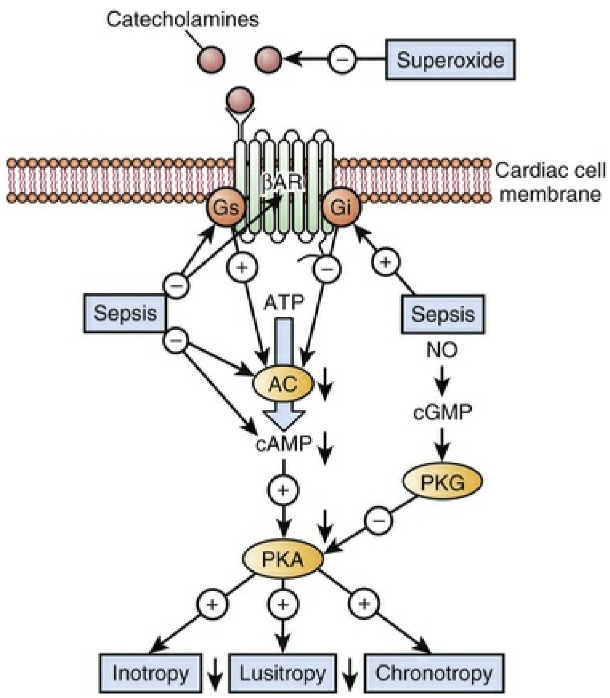

FIG. 125.15 Sepsis-induced alterations in the β-adrenergic signaling cascade. *AC*, adenylate cyclase; *ATP*, adenosine triphosphate; *βAR*, β-adrenergic receptor; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; G_i, inhibitory G protein; G_s, stimulatory G protein; *NO*, nitric oxide; *PKA*, protein kinase A; *PKG*, protein kinase G. (Modified from Rudiger A, Singer M. Mechanisms of sepsis-induced cardiac dysfunction. Crit Care Med. 2007;35:1599-1608.)

Conclusion

Even though knowledge of how drugs work at a molecular level has grown tremendously, continued elucidation of normal signal transduction physiology and of the effects of genetics, development, and disease states on the functional integrity of receptors, signaling pathways, and effectors should improve and refine pharmacologic interventions administered to critically ill children. To optimize the efficacy/toxicity ratio, both genetic and nongenetic factors, including the patient's age, sex, organ function, ethnicity, concomitant therapy, drug interactions, nature and severity of the disease, comorbid conditions, and the use of extracorporeal device (eg, extracorporeal membrane oxygenation), should be taken into account so as to individualize pharmacotherapy in the pediatric intensive care unit setting.

CHAPTER 126

Adverse Drug Reactions and Drug-Drug Interactions

Wade W. Benton, Christa C. Jefferis Kirk, Tsingyi Koh, Gretchen A. Linggi Irby

PEARLS

- Overall, the incidence of adverse events in pediatric inpatients can range from 4.4% to 16.8% of hospital admissions, which is higher than the estimated incidence of approximately 4% in adults.
- Developmental differences in drug disposition and clearance in pediatrics increase the potential of adverse drug reactions (ADRs) in comparison to adults.
- The economic impact from drug-related morbidity and mortality from ADRs is estimated to be approximately $137 billion to $177 billion. Pediatric ADRs nationally have an estimated economic burden of approximately $252.9 million.
- Drug-drug interactions are mediated via pharmacokinetic and pharmacodynamic properties of medications. Increased awareness of common mechanisms of interaction can aid the clinician in avoiding or ameliorating unwanted adverse effects.
- The pediatric intensive care provider is confronted daily with potentially hazardous drug-drug interactions in the critical care setting. It is nearly impossible to recognize every potential drug-drug interaction in the pediatric critical care setting; however, in most cases, drug-drug interactions are predictable and preventable, with appropriate dosage modifications or avoidance of combinations.

Adverse drug reactions (ADRs) in pediatric critical care settings can increase both the morbidity and mortality of patients as well as hospital costs.[1,2-4] Literature suggests the economic impact from drug-related morbidity and mortality from ADRs is estimated to be approximately $137 billion to $177 billion.[4] Pediatric adverse drug events (ADEs) nationally have an estimated economic burden of approximately $252.9 million.[4] Epidemiologic studies for ADRs confirm that the problem is just as

important for children as it is for adults.[1,2,5-8] In comparison to adults, developmental differences in drug disposition and clearance in pediatrics increase the potential for ADRs. There is substantial evidence that the incidence of adverse drug reactions is greater in children than in adults. Many of the therapeutic agents used in the pediatric critical care setting have not been studied and evaluated for safety and efficacy in pediatric patients. Intensive care physicians should have a heightened awareness of the incidence of ADRs so they can assist with recognizing, monitoring, and, ultimately, preventing ADRs. Patients in the intensive care unit are predisposed to ADRs due to the heightened incidence of single and multiple organ failure. Key risk factors include age <1 year, polypharmacy, and impairment of metabolism or drug excretion.[4] To recognize and prevent ADRs, pediatric intensivists need to be aware of the complications associated with drug therapy.

Preventive measures can decrease the occurrence of ADRs. Overall, the incidence of adverse events in pediatric inpatients can range from 4.4% to 16.8% of hospital admissions, which is higher than the estimated incidence of approximately 4% in adults.[4,9,10] Although steps have been taken to reduce ADRs, there are still issues that cause children to be more susceptible. Weight-based dosing and dilution needed for administration of parenteral therapy combined with the fact that sick infants and children may have a reduced ability to survive iatrogenic events create a larger risk of ADRs in the pediatric population.

One of the difficulties in interpreting literature on ADRs is how they are defined. The World Health Organization (WHO) and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) have varying definitions for ADRs. The American Society for Health-System Pharmacists (ASHP) defines a significant adverse drug reaction as any unexpected, unintended, undesired, or excessive response to a drug that does the following[11]:

- Requires discontinuing the drug (therapeutic or diagnostic)
- Requires changing drug therapy
- Requires modifying the dose (except for minor dosage adjustments)
- Necessitates admission to a hospital
- Prolongs stay in a health care facility
- Necessitates supportive treatment
- Significantly complicates diagnosis
- Negatively affects prognosis
- Results in temporary or permanent harm, disability, or death

ASHP also defines other symptoms that are not considered true adverse drug reactions:

- Side effects
- Drug withdrawal
- Drug abuse syndrome
- Accidental poisoning
- Drug overdose complications

For reporting purposes, the Food and Drug Administration (FDA) categorizes a serious adverse event (an event relating to drugs and devices) as one in which "the patient outcome is death, life-threatening (real risk of death), hospitalization (initial

or prolonged), disability (significant, persistent, or permanent), congenital anomaly, or required intervention to prevent permanent impairment or damage."[12]

A critical factor in assessing ADRs is establishing a causal relationship between the suspected drug and the adverse reaction.[15] Identification of ADRS can be arbitrary. Some of the confounding factors are the ambiguous characteristics of the reactions, the fact that patients usually are taking more than one medication at the time of the reaction, and the inability to perform definitive cause-and-effect tests.[15] There have been numerous attempts to formalize the process.[15-21] Karch and Lasagna designed decision tables that can identify a potential reaction, assess the certainty of a link between the drug and the event, and evaluate the underlying cause of the reaction.[15] These provide a framework for a systematic evaluation of potential ADRs and reduce the ambiguity that, at present, characterizes their assessment. Kramer and associates devised an operational assessment using an algorithm with six axes to assess the probability of an ADR occurrence. A scoring system for each axis and an overall score help delineate the likelihood that an ADR has occurred.[18] Similarly, Naranjo and colleagues developed an adverse drug reaction probability scale using 10 questions answered positively, negatively, or unknown to determine the likelihood that an ADR had occurred. The Naranjo method has been shown to improve the reproducibility of ADR assessments.[16]

An FDA algorithm that assesses the characteristics of the event (temporal relationship, dechallenge, rechallenge, and relationship to disease) has been presented.[17] The algorithm contains four questions to assess the likelihood that an adverse drug reaction had occurred:

1. Did the reaction follow a reasonable temporal sequence?

2. Did the patient improve after stopping the drug?

3. Did the reaction reappear on repeated experience (rechallenge)?

4. Could the reaction be reasonably explained by known characteristics of the patient's clinical state?

The categories *remote, possible, probable,* and *highly probable* are used based on the answers to the four questions.

Once an ADR is identified, appropriate reporting is critical. Reporting can occur by several mechanisms. The event can be reported through the health care system's ADR program, which is typically organized by the pharmacy department. Another avenue is to contact the drug manufacturer directly, as all companies have a mechanism for documenting ADRs. Finally, severe and significant reactions should be reported immediately to the FDA through the MedWatch program (http://www.fda.gov/Safety/MedWatch/).

Adverse Drug Reactions by Organ System

Renal

Nephrotoxicity accounts for nearly 7% of all adverse drug reactions.[10] Several factors place the renal system at risk for adverse drug reactions. The renal system is

responsible for eliminating many drugs and metabolites, of which several are known nephrotoxins. Additionally, the renal vascular system receives approximately 20% to 25% of resting cardiac output. Therefore the kidneys are exposed to high concentrations of drugs and diagnostic agents. Although the renal system is highly vulnerable to nephrotoxicity, there are only a few mechanisms by which nephrotoxins can induce injury. These mechanisms include hemodynamically mediated nephrotoxicity, tubular necrosis, interstitial nephritis, obstructive nephropathy, and vascular toxicity. Many nephrotoxins can injure the kidney through more than one mechanism.

A variety of drugs are associated with acute tubular necrosis, including aminoglycosides, cisplatin, amphotericin B, radiocontrast media, cyclosporine, and intravenous (IV) immunoglobulins.[21-23] Acute tubular necrosis is one of the most common renal disorders associated with drug therapy. Minimizing risk factors for nephrotoxicity with these agents is imperative. For example, administrations of a saline load and volume repletion have been shown to be beneficial in reducing toxicity.[24] Table 126.1 presents a more complete list of medications associated with tubular necrosis.

TABLE 126.1

Drugs Causing Nephrotoxicity

Tubular Necrosis	Interstitial Nephritis	Hemodynamic-Mediated Renal Failure
Aminoglycosides	Allopurinol	Angiotensin-converting enzyme inhibitors
Amphotericin	Aminoglycosides	Cyclosporine
Carboplatin	Aztreonam	Mannitol
Cephalosporins	Captopril	NSAIDs
Cisplatin	Carbamazepine	Propranolol
Cyclosporine	Cephalosporins	Radiologic contrast agents
Mannitol	Cimetidine	Tacrolimus
Methoxyflurane	Ciprofloxacin	
NSAIDs	Cyclosporine	
Pentamidine	Erythromycin	
Radiologic contrast agents	Interferon-α	
	NSAIDs	
	Penicillins	
	Phenobarbital	
	Phenytoin	
	Ranitidine	
	Rifampin	
	Sulfonamides	
	Tacrolimus	
	Thiazide and loop diuretics	
	Valproic acid	
	Vancomycin	
	Warfarin	

NSAID, nonsteroidal antiinflammatory drug.

Several drugs are implicated in the alteration of renal blood flow. Some of the most common include angiotensin-converting enzyme inhibitors (ACEIs), nonsteroidal antiinflammatory drugs (NSAIDs), β-adrenergic antagonists, and calcineurin inhibitors.[7,25-32] ACEIs can induce renal insufficiency in patients suffering from any process that decreases renal blood flow, including bilateral renal artery stenosis or unilateral stenosis with a single kidney.[33] The mechanism involves inhibiting the conversion of angiotensin I to angiotensin II, which results in dilation of the efferent arterioles, with resultant decreased glomerular capillary hydrostatic pressure and reduced glomerular filtration. The incidence of ACEI-induced renal

failure in patients with renovascular hypertension ranges from 20% to 38%.[31] NSAIDs inhibit prostaglandin synthesis, which leads to reduced renal blood flow and reduced glomerular filtration. The incidence of renal insufficiency is most common in patients with chronic renal disease, hypovolemia, sepsis, and those who use concomitant nephrotoxic drugs.[25,27,28,30,32,34] NSAID-induced renal toxicity is reversible if the toxic agent is discontinued immediately.[33] Table 126.1 provides a more complete list of drugs associated with hemodynamic renal failure.

Acute interstitial nephritis is another common source of drug-induced nephrotoxicity. It is reported to cause 3% to 8% of all cases of acute renal failure.[35] The clinical presentation of acute interstitial nephritis can appear anywhere between 2 and 44 days after initiation of the offending therapy.[36,37] Typical clinical symptoms include fever, skin rash, and flank tenderness.[36,37] Common laboratory findings include hematuria, sterile pyuria, and eosinophilia.[38] Histologic findings of acute interstitial nephritis include interstitial infiltrate of lymphocytes, plasma cells, eosinophils, and neutrophils.[36-38] Prompt discontinuation of the offending drug from therapy is recommended, and administration of corticosteroids may improve recovery.[39] Table 126.1 lists some medications associated with acute interstitial nephritis.

Renal tubular obstruction is associated with precipitation of endogenous products, drugs, and their metabolites. Formation of uric acid precipitant after chemotherapy can result in renal obstruction. Hydrating patients prior to chemotherapy, urinary alkalization, and use of allopurinol or rasburicase can help prevent uric acid precipitation.[40] Rhabdomyolysis can cause intratubular precipitation of myoglobin and lead to acute renal failure. Terbutaline overdose has resulted in rhabdomyolysis-induced renal failure.[41] Drugs associated with formation of crystals include acyclovir, sulfonamides, mannitol, pentobarbital, methotrexate, and dextran.[40,42-44]

Aminoglycosides are used frequently for treatment of gram-negative infections. All aminoglycosides have been shown to be toxic to the proximal renal tubules.[45] Aminoglycoside nephrotoxicity is related to dose, high trough concentrations, and prolonged therapy.[45] The drug-induced nephrotoxicity normally manifests as nonoliguric renal failure.[46] Several risk factors for developing aminoglycoside nephrotoxicity include the need for intensive care, decreased albumin, poor nutritional status, prolonged therapy, hypovolemia, pneumonia, shock, preexisting liver or kidney disease, and elevated initial steady-state drug concentrations.[46,47] Additionally, vancomycin, piperacillin, furosemide, amphotericin B, and cephalosporins, when administered concomitantly with aminoglycosides, are associated with an increased risk for developing nephrotoxicity.[46] Predicting nephrotoxicity based on the risk factors stated is an extremely complicated, inexact task.[46,48] Typically, aminoglycoside nephrotoxicity is reversible upon discontinuation of the offending agent.[45,49]

Drug-induced nephrotoxicity is a common serious adverse drug reaction that can lead to morbidity and lengthen hospital stays.[50] It is important to recognize potential nephrotoxins before initiating therapy and to evaluate therapeutic options. It is also important to monitor therapy appropriately for signs of toxicity and to modify therapy as needed.

Hepatic

The liver is the most common target of drug toxicity due to its major role of metabolism and elimination of foreign substances. It is well documented that acetaminophen causes intrinsic hepatotoxicity following acetaminophen overdose; however, a variety of medications can cause drug-induced hepatotoxicity. It often is difficult to determine the source of unexplained liver injury, so detailed examination of past and current drug therapies is needed to rule out possible drug-related causes. Most hepatotoxicity associated with drugs is idiosyncratic in nature and has a rate usually fewer than 1 per 10,000 exposed patients. The pathogenesis of drug-induced liver disease is mediated through either an immune response or direct cell damage.[51,52] In many cases, this hepatotoxicity is idiosyncratic, meaning not predictable or dose related, in contrast to drugs like acetaminophen and isoniazid for which toxicity is related to dose.[51,52]

The mechanism of toxicity for drug-induced liver injury generally involves the accumulation of drugs or their metabolites, which can cause direct cell damage, target mitochondrial function, or trigger an immune response. The initial stress or immune reaction leads to a mitochondrial permeability transition, which is either a direct pathway, mediated by cell damage, or is triggered by the death receptor amplified pathway. The mitochondrial impairment will determine if the hepatocytes die by apoptosis or necrosis. Measurements of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and total bilirubin are important in assessment of drug-induced liver injury. It has been estimated that one-tenth of the Hy's law cases with hyperbilirubinemia or jaundice die or require transplant.[53,54] In severe cases of drug-induced hepatic injury, jaundice and hepatic failure may ensue.[52] Typically, drug-induced hepatic disease occurs expectedly as a result of high-dose therapy of a known hepatotoxin or unexpectedly as a result of an idiosyncratic reaction to a drug not associated with hepatotoxicity. Overall, children are less prone to drug-induced liver disease than are adults.[55] However, specific hepatotoxins have been shown to afflict children more than adults. Reye syndrome is a hepatocellular disease that has been associated with aspirin use in children.[56] Valproate hepatotoxicity occurs more frequently in children younger than 2 years who have preexisting neurologic or physical defects.[57]

Drug-induced hepatic disease can occur by a variety of mechanisms, including by hepatocellular, cholestatic, and vascular means. These injuries are associated with intrinsic or idiosyncratic hepatotoxins. Intrinsic hepatotoxins typically show a dose-related toxic effect. Idiosyncratic hepatic disease is an unpredictable reaction that can occur by immune-mediated hypersensitivity, metabolically, or both. Hypersensitivity reactions in the liver can cause cell injury to hepatocytes. The reactions do not correlate with dose and are difficult to anticipate. This immune-mediated reaction results from antigenic complexes that stimulate T lymphocytes, which can result in hepatic injury. These reactions can be accompanied by fever, skin rash, lymphadenopathy, and eosinophilia.[52] The reactions typically resolve upon discontinuation of therapy and resurface when therapy is rechallenged.[52] Metabolic idiosyncrasy occurs when a compound that is metabolized to nontoxic metabolites and eliminated in the majority of patients is metabolized to a toxic metabolite in a small number of patients because of genetic differences in metabolism (such as with isoniazid).[57] Box 126.1 lists a number of agents that are associated with drug-induced hepatotoxicity.

Box 126.1

Drugs That Cause Hepatotoxicity

Acetaminophen

Amoxicillin-clavulanic acid

Carbamazepine

Tetracyclines

Trazodone

Valproate

Voriconazole

Cardiovascular

An adverse cardiovascular reaction has been noted to be one of the most common types of ADE in pediatric patients.[58] Several medications are associated with adverse cardiovascular effects, and the mechanisms are often thought to be related to the agents' pharmacologic actions. These effects are potentiated by four general physiologic pathways: electrolyte and fluid imbalances, receptor-mediated sympathomimetic effects, alterations of the electrophysiology of the cardiac tissue, and drug-induced cardiotoxicity.

Medications can affect electrolyte and volume status by direct action on electrolyte receptors or indirect effects on prostaglandin release and the renin-angiotensin-

aldosterone system. Dramatic changes in fluid and electrolyte status can lead to severe changes in blood pressure, heart rate, or cardiac rhythms. Medications that can potentiate histamine release such as morphine, fentanyl, and succinylcholine may also affect fluid and electrolyte status, causing hypotension if significant capillary leak develops.[59-62] Nonsteroidal antiinflammatory drugs, corticosteroids, diuretics, erythropoiesis-stimulating agents, estrogen-containing oral contraceptives, mannitol, and certain immunosuppressive agents, such as cyclosporine and tacrolimus, are all medications that can alter fluid and electrolyte balance.[52,62-65]

Pediatric patients in the intensive care unit often require vasopressive medications; however, it is important to be aware that many cardiovascular toxicities have been observed with the use of vasopressors, and most of these toxicities stem from their receptor-mediated effects (Table 126.2). The α-adrenergic agonism of the sympathomimetics causes palpitations, ectopic heartbeats, sinus tachycardia, and ventricular arrhythmias producing an increase in myocardial oxygen demand.[66] Other medications that may have sympathomimetic effects include caffeine, pseudoephedrine, and abrupt withdrawal of β-blockers and centrally acting α-agonists such as clonidine.[67] Increased myocardial oxygen demand may precipitate an infarction, especially in individuals with underlying cardiac disease. A dramatic rise in heart rate and peripheral vascular resistance may produce severe hypertension. Excessive α-adrenergic stimulation may produce vasoconstriction so severe in the extremities, kidneys, or liver that tissues become ischemic or necrotic. Specifically, vasopressin can cause such severe vasoconstriction that it has been associated with digital loss and splanchnic ischemia.[23] One study noted that 10% of patients receiving norepinephrine and vasopressin developed severe vasoconstriction-related adverse events, including acute kidney injury, which increased the risk of mortality twofold.[23] The sedative dexmedetomidine, though not classified as a vasopressor, has α_2-adrenergic agonist properties and effects similar to the medication clonidine. When using dexmedetomidine, it is important to monitor patients for hypotension, arrhythmias, and bradycardia.[65]

TABLE 126.2

Adverse Effects of Vasopressor Medications by Adrenergic Receptor Affinity

Medication	Affected Adrenergic Receptor	Associated Adverse Effect
Dopamine	5-10 mcg/kg/min: β_1 >10 mcg/kg/min: β_1 and α (mostly alpha)	Vasoconstriction, tachycardia, arrhythmias Extravasation causes ischemia
Dobutamine	β_1: selective	Increased heart rate, arrhythmias, ↑ myocardial oxygen demand
Epinephrine	<0.5 mcg/kg/min: β_1 >0.5 mcg/kg/min: α	Vasoconstriction, tachycardia, arrhythmias, tissue ischemia, cerebral hemorrhage, ↑ myocardial oxygen demand Extravasation causes necrosis
Isoproterenol	β: nonselective ($\beta_1 > \beta_2$)	Tachycardia, arrhythmias, hypotension, ↑ myocardial oxygen demand
Norepinephrine	α	Potent vasoconstriction, arrhythmias, tissue ischemia Extravasation causes necrosis
Phenylephrine	α	Systemic vasoconstriction, hypertension, bradycardia
Vasopressin	V1 vascular receptor	Potent vasoconstriction, tissue ischemia

Adapted from Goembiewski JA. Vasopressors used in the critical care setting. J Peri Anesth Nurs. 2003;18:414-416; Vetter VL, ed. Pediatric Cardiology: The Requisites in Pediatrics. Philadelphia: Mosby Elsevier; 2006.

As noted previously, many medications produce arrhythmogenic effects through

various mechanisms of action that can increase morbidity and mortality. Ventricular arrhythmias in infants and children, unlike adults, are relatively uncommon. The most commonly reported arrhythmias in pediatric patients include conduction disturbances or supraventricular arrhythmias including atrial tachycardia, junctional tachycardia, and sinus bradycardia. Due to the narrow therapeutic index of its concentration in the blood, digoxin, a direct-acting cardiac glycoside, is often associated with a variety of arrhythmias.[23] Close monitoring of electrolytes, especially potassium, renal function, and drug levels, helps to prevent adverse effects associated with digoxin. Another class of medications that requires close ECG monitoring is the antiarrhythmic medications. These medications have mechanisms of action that manipulate cardiac action potential and therefore have the ability to produce dysrhythmias.[66,68] Often used to treat supraventricular tachyarrhythmias, amiodarone is associated with bradycardia and hypotension, which may be dose and infusion rate dependent.[23] β-Blockers are also used as antiarrhythmic medications; however, they can lead to the development of life-threatening bradycardia at higher doses as well. Therefore it is recommended that treatments begin with lower doses and titrate slowly to the lowest effective dose.[69] Though previously a cause for concern, the stimulant medications commonly used to treat attention deficit and hyperactivity disorder (ADHD) no longer require extensive cardiac evaluation prior to initiation of therapy in patients without the presence, or significant risk, of underlying cardiac disease.[23] However, atomoxetine, a selective norepinephrine reuptake inhibitor often used in place of stimulant medications for ADHD, has been associated with a measurable increase in heart rate and blood pressure. Therefore the FDA recommends use with caution in patients with underlying cardiac disease.[23]

Although ventricular arrhythmias are uncommon in pediatric patients, the risk of torsades de pointes is still of concern in this population. Torsades de pointes is a life-threatening subset of arrhythmias and is characterized on electrocardiogram by lengthening of the QT interval and waxing/waning QRS amplitude. Certain medications can increase the risk for this arrhythmia by blocking potassium conductance on the rapid (Ikr) and slow (Iks) receptors within potassium ion channels. This creates a delayed ventricular repolarization and can lead to multiple ventricular reentrant loops. Risk factors for drug-induced torsades de pointes include high doses of associated medications (Box 126.2), concurrent use of multiple QT-prolonging medications, underlying structural heart disease including heart failure, ECG changes such as a prolonged QT interval at baseline or bradycardia, presence of hypokalemia or hypomagnesemia, and female sex.[70,23] Most commonly, antiarrhythmics, antipsychotics, antidepressants, azole antifungals, and fluoroquinolones are general classes of agents that demonstrate the potential to prolong the QT interval.[71,72] Another concern when administering these medications is pharmacokinetic drug-drug interactions or pathophysiologic alterations in elimination. Any biochemical mechanism that increases the concentration by inhibition of cytochrome isozymes or decreased clearance of the associated medication has the ability to potentiate this type of arrhythmia.[73] Current practice guidelines recommend avoiding high-risk medications if the patient has a baseline QTc greater than 450 msec and to discontinue or reduce the dose of the medication if the QTc increases by ≥60 msec from baseline or greater after initial medication administration.[74] Additionally, all efforts should be made to avoid drug-drug

interactions and combinations of medications that can be known to precipitate torsades de pointes. A 12-lead ECG should be attained prior to the initiation of high-risk medications or combinations of medications. ECGs should be monitored at least daily until the full effect has been evaluated.[74] Data have suggested that administration of magnesium prior to giving high-risk intravenous medications may attenuate the effects of QT prolongation; however, this effect has not been confirmed by larger trials. Therefore this strategy should be limited to situations where there may be no other alternative.[75]

[b]Medications moderately associated with QT prolongation.
[c]Cisapride, though removed from the US market, has been approved for limited compassionate use in some pediatric disease states.

Medication-induced heart failure may be caused by a reduction in myocardial contractility, increase in preload, or oxidative damage leading to myocyte death. Tricyclic antidepressants, calcium channel blockers, β-blockers, and some antiarrhythmics exert a negative inotropic effect, decreasing contractility, which may lead to acute heart failure. Medications that cause fluid retention, such as NSAIDS, can slowly increase preload, which may cause heart failure with chronic use.[76-78] In patients with underlying heart failure or those at risk for heart failure, attempts should be made to limit the use of these medications. If unavoidable, clinicians are recommended to use the lowest possible effective dose.

Cyclophosphamide, trastuzumab, interferon alfa, and anthracycline antineoplastic agents directly affect myocyte cells and damage cardiac tissue.[79-81] Anthracyclines, such as doxorubicin, epirubicin, idarubicin, and mitoxantrone, may lead to acute cardiotoxicity, manifesting as arrhythmias, or cardiomyopathy, which is related to a cumulative lifetime dose. These defects include abnormal right ventricular wall motion, impaired myocardial contractility, conduction abnormalities, and congestive heart failure.[82] There may also be delayed development of cardiotoxicity, as children who have received anthracycline therapy may see symptoms anywhere between 4 and 20 years after exposure.[82] Severe anthracycline toxicity cannot be reversed, and such a diagnosis leads to a poor prognosis and high mortality.[82] Strategies to minimize anthracycline toxicity include documenting and limiting total lifetime dose, supplements such as coenzyme Q10 and carnitine, pretreatment with antihistamines, increased infusion time, use of liposomal anthracyclines, and dexrazoxane. Dexrazoxane, a derivative of EDTA, binds free radicals produced by anthracyclines preventing oxidative damage to the myocyte. Its use is reserved for patients whose diagnoses typically require higher cumulative lifetime doses of

anthracyclines.[83]

Central Nervous System

Prescription medications are the most common cause of iatrogenic seizures.[84] Drug-related factors that may contribute to seizures include the intrinsic epileptogenicity of the agent, factors that influence serum levels (dose, schedule, route), and factors that affect central nervous system (CNS) drug levels (lipid solubility, molecular weight, ionization of the drug, protein binding, transport by endogenous systems).[85] Patient-related factors may influence the risk for drug-induced seizures, such as preexisting epilepsy, neurologic abnormality, decreased drug elimination capacity (renal, hepatic), and conditions that disrupt the blood-brain barrier.[85] Several medications used within the intensive care unit have been associated with seizures. Due to the complexity of care needed for intensive care patients, increasing practitioner awareness of these medications, as well as their mechanisms of action, should allow practitioners to recognize and diagnose drug-induced seizures more effectively (Table 126.3).

TABLE 126.3

Medications That Can Induce Seizures

Medication	Potential Mechanism of Action	Comments
Acyclovir[312]	Neurotoxicity	Renal impairment and parenteral administration increase the incidence
Antipsychotics[313]	Decreases seizure threshold	Increased incidence with high doses and rapid dose adjustments
Carbapenems[314]	Potentiates seizure activity through the inhibition of GABA receptor	Caution in patients with CNS disorders and renal dysfunction Imipenem has higher incidence compared with meropenem, ertapenem, doripenem
Cephalosporins[315]	Inhibition of GABA receptor	Ceftazidime > ceftriaxone > cefuroxime and cefotaxime
Cyclosporine[316]	Unknown but may involve the release of the potent vasoconstrictor endothelin from endothelial cells, which induce microvascular damage or changes in permeability of the blood-brain barrier	More common with high doses Increased incidence with hypercholesterolemia and hypomagnesemia
Cytarabine[317]	Cerebral dysfunction	Increased incidence with intrathecal administration
Flumazenil[319]	May precipitate benzodiazepine withdrawal; inhibition with seizure medications	Use in caution with patients with underlying seizure disorder
Fluoroquinolones[318]	Unknown but may involve inhibition of GABA receptor	History of seizures and use of NSAIDs associated with increased risk of seizures
Meperidine[313]	CNS excitation from toxic metabolite (normeperidine); blockade of serotonin	Common reaction with renal impairment and high doses
Metronidazole[315]	Penetrates the blood-brain barrier	Cumulative high dose and prolonged use
Penicillins[320]	Irritation of nervous system	Use with caution in infants, rapid IV infusions, and renal impairment
Tacrolimus[321-323]	Neurotoxicity	May be secondary to local vasoconstriction mediated by endothelin; elevated levels and hepatic impairment may increase the risk of neurotoxicity
Theophylline[313]	CNS toxicity	Serum concentrations >25 μg/mL have been noted to induce seizures

Many medications can increase the risk of seizure exacerbation or development in ICU patients. Meperidine may induce seizures, especially in patients with renal insufficiency, due to accumulation of its metabolites.[84] Rapid administration of fentanyl is associated with seizures.[84] Several antiinfective and immunosuppressive

medications including β-lactam antibiotics, imipenem, high-dose metronidazole, isoniazid, and cyclosporine induce seizures.[84] Many of the antiepileptic drugs can be implicated in worsening seizure activity, which usually occurs when higher than normal concentrations are used. Seizures also may be precipitated by medication withdrawal. Withdrawal of antiepileptic agents may cause seizures due to either subtherapeutic levels or excessively rapid removal of the agent.[85]

Delirium in critically ill patients remains a significant issue and is associated with negative outcomes, longer ICU stays, and increased costs.[86,87] The risk factors for ICU delirium are multifactorial and debatable. Emerging evidence suggests sedative practices may influence and contribute to the development of delirium, especially the use of benzodiazepines. Further studies and increasing awareness among pediatric intensivists should help to prevent delirium. Several medications are associated with ototoxicity, which is usually iatrogenic.[88] The main sites of action of ototoxic drugs are the cochlea, vestibulum, and stria vascularis.[89] Salicylates and aminoglycosides are the most common agents associated with hearing loss.[87,88] Other agents include cisplatin, loop diuretics, erythromycin, and vancomyin.[89,90] The effect is usually dose dependent.[88-90] High-dose and long-term therapy are common risk factors for aminoglycoside-induced ototoxicity.[89,90] Cisplatin is the most ototoxic of the antineoplastic agents, whereas ethacrynic acid has the greatest potential for causing ototoxicity in the loop diuretic category.[90] Appropriate dosing and monitoring of agents associated with ototoxicity are important for prevention and early detection.

Hematologic

Chemotherapy with cytotoxic agents is the most common cause of drug-induced bone marrow suppression and can lead to secondary morbidities. For example, neutropenia predisposes a patient to opportunistic infections and sepsis. Chemotherapy-induced thrombocytopenia may render a patient vulnerable to hemorrhage in the CNS or gastrointestinal (GI) tract. Severe anemia may lead to dizziness, fatigue, hypotension, and myocardial infarction.[91] In addition to bone marrow suppression, some antineoplastics may produce thrombotic and hemorrhagic coagulation toxicities. For example, L-asparaginase has been reported to induce changes in the von Willebrand factor multimer in children and thereby promote platelet aggregation.[82]

Drug-induced myelosuppression has also been observed with several classes of antiinfectives such as β-lactam antibiotics, linezolid, trimethoprim-sulfamethoxazole, chloramphenicol, and antiviral agents.[92] β-Lactam antibiotics have been reported to be associated with autoimmune hemolytic anemia, leukopenia, and thrombocytopenia.[92,93] Linezolid-induced thrombocytopenia and anemia is most commonly seen when therapy continues for >2 weeks.[92,93] However, these effects are reversible upon discontinuation of therapy. The manufacturer recommends weekly monitoring of complete blood counts, especially for patients who require treatment beyond 2 weeks. Neutropenia is a common side effect associated with the use of ganciclovir and valganciclovir. In addition, these medications are commonly used in immunosuppressed patients who are often on concurrent marrow suppressive agents. Close monitoring of neutrophil counts in these patients is prudent to prevent neutropenia-associated complications. These antiviral medications should be renally adjusted as appropriate to prevent neutropenia. However, it is important to note that

dose adjustments should not be made based on neutrophil counts, as it may lead to subtherapeutic drug levels and the potential for drug resistance.

Respiratory

Respiratory adverse effects are relatively uncommon but are among the most serious adverse events. Due to the seriousness of some of the drug-induced respiratory adverse events, which can be life threatening, intensive medical interventions are often required. Numerous agents have been known to cause lung disease. In 1975, only 19 agents were implicated with pulmonary complications.[94,95] More than 350 agents have now been identified as having the potential to induce respiratory complications.[94,95] The number of agents known to cause pulmonary adverse reactions continues to expand each year. Recognition of drug-induced pulmonary disease may be challenging due to the presence of confounding variables often associated with ICU patients, which may result in the underdiagnosis of both acute and chronic lung disease.[96] Some of the confounding factors in the diagnosis of drug-induced pulmonary disease include preexisting pulmonary conditions such as bronchopulmonary dysplasia and asthma, the use of oxygen, and concurrent medications.[97,98]

The two main risk factors for the development of drug-induced bronchospasm include a previous history of reactive airway disease and chronic obstructive lung disease.[98,99] There are several classes of medications associated with this clinically significant reaction. Analgesics and NSAIDs are two of the most common medications that can precipitate bronchospasm.[99] Other agents include antimicrobials (eg, sulfonamides), cardiovascular agents (eg, β-blockers and ACE inhibitors), and excipients (eg, preservatives, coloring agents, antioxidants).[99] The extensive list of medications suspected of causing or exacerbating bronchospastic reactions demonstrates the need to be aware of drug-induced causes of acute episodes, especially in patients with a history of preexisting lung conditions.

Opiates are commonly prescribed to pediatric intensive care patients. Acute respiratory failure secondary to a noncardiogenic pulmonary edema has been reported with the use of opiates including methadone, morphine, and codeine.[100] Aspirin has also been identified to cause pulmonary toxicity. High concentrations of aspirin can lead to increased vascular permeability causing pulmonary edema. A syndrome of massive fluid retention and pulmonary edema may be seen with interleukin-2 administration. All-trans-retinoic acid may cause acute lung disease secondary to massive total body fluid accumulation.

Chronic pneumonitis/fibrosis is a relatively common syndrome associated with drug-induced pulmonary reactions and is manifested by slowly progressive symptoms of cough and dyspnea.[100] Nitrofurantoin is associated with pulmonary fibrosis, most commonly in patients receiving chronic, high-dose therapy or patients with renal insufficiency.[101] A delayed presentation (months to years after discontinuation of or the start of therapy) is the most common form of fibrosis seen with amiodarone, but it also may cause an acute fibrosis manifesting within the first few weeks of therapy.[101,102] Many cytotoxic agents have been known to cause pulmonary fibrosis including bleomycin, carmustine, mitomycin, mitomycin with vinca alkaloid combination therapy, and cyclophosphamide. Risk factors for this reaction to cytotoxic agents include cumulative dose, age at initiation of treatment,

and concomitant radiation therapy.

Endocrine and Metabolic

Due to the complexity of the biochemical processes that influence the endocrine and metabolic balance of the body, several medications have the potential to create alterations in neuroendocrine hormonal production, binding, transport, and signaling. Additionally medications may create changes in hormonal counterregulatory efforts. The most common types of medication-induced endocrine disorders are modifications in carbohydrate metabolism, electrolyte and calcium abnormalities, drug-induced thyroid changes, and alterations in acid-base status.[99] Variations in carbohydrate metabolism are commonly seen with many medications and are clinically manifested as alterations in blood glucose. Table 126.4 lists the multitude of medications associated with hypoglycemia or hyperglycemia subdivided by neuroendocrine effect.[103-107,108-113]

TABLE 126.4

Drugs That Cause Endocrine/Metabolic Changes

ACE, angiotensin-converting enzyme; *ARBs*, angiotensin II receptor blockers; *HAART*, highly active antiretroviral therapy; *NSAIDs*, nonsteroidal antiinflammatory drugs; *SIADH*, syndrome of inappropriate antidiuretic hormone.

Hypoglycemia occurs most commonly as a result of overtreatment with insulin or diabetic medications, whereas hyperglycemia results from medications that either increase glucose production or decrease the effects of exogenous insulin.[103,114,115] Decreased insulin secretion, changes in liver glucose metabolism and production, and increased insulin resistance are the most common mechanism of drug-induced hyperglycemia.[103] Glucocorticoid usage is commonly associated with hyperglycemia and glycosuria.[116] Corticosteroids increase blood glucose via hepatic gluconeogenesis and by increasing peripheral insulin resistance.[117] This adverse drug reaction appears to be dose dependent and usually is reversible upon discontinuation of therapy.[117] Patients on high-dose, long-term glucocorticoid therapies are at significant risk for suppression of the hypothalamic-pituitary-adrenal axis.[118,119] Symptoms of adrenal insufficiency include arthralgias, dizziness, hypotension, nausea, and weakness.[118]

Drug-induced electrolyte disturbances can occur with a variety of pharmaceutical agents. Several medications are associated with initial or worsening hypokalemia, hyperkalemia, hyponatremia, hypernatremia, and hypomagnesemia (see Table 126.4).[103,120-135]

Hyponatremia and hypernatremia are often secondary to depletion or dilutional effects of medications or drug-induced changes in antidiuretic hormone.[103,122] Additionally, some medications, such as trimethoprim-sulfamethoxazole, can cause renal salt wasting.[136] Hypokalemia is directly affected by medications that increase potassium excretion or increase Na-K-ATPase activity, causing potassium influx into the cells. Drug-induced hyperkalemia can develop when medications lead to decreased Na-K-ATPase activity, aldosterone deficiencies, and resistance to aldosterone.[103,120] Succinylcholine, however, has a different mechanism of action for increasing serum potassium by directly affecting ion-channel depolarization.[136] Medications that affect the renal tubules of the kidneys, such as amphotericin B and cyclosporine, have been associated with severe hypomagnesemia, which can also play a role in hypokalemia.[136,124] Often, correcting serum magnesium can be beneficial for normalizing other electrolyte levels, such as potassium and calcium. Antiepileptic agents, citrated solutions, foscarnet, and intravenous diltiazem have all been associated with critical hypocalcemia due to effects on vitamin D metabolism or calcium reuptake mechanisms.[125-131] Electrolyte disorders represent a common adverse drug reaction and can greatly complicate therapy. Accordingly, frequent monitoring of electrolytes is warranted for patients in the ICU on multiple drug therapy.

Electrolyte abnormalities have been noted with the use of amiodarone; however, it is most commonly known for its adverse effects on the thyroid gland. Due to the large amount of iodine in amiodarone (3 mg of iodine/100 mg of drug), it has a counterregulatory effect on the production of thyroid hormones.[103] In patients in more developed countries, where iodine deficiency is rare, use of amiodarone is associated with hypothyroidism; however, in countries where iodine deficiency is

more common; amiodarone can cause thyrotoxicosis.[133,134] It is important to obtain baseline thyroid studies prior to starting therapy and to monitor them continually throughout treatment.

Although uncommon, prolonged use of nitroprusside can result in methemoglobinemia and cyanide or thiocyanate toxicity.[137,138] The risk of thiocyanate or cyanide toxicity is higher in patients with renal dysfunction, hepatic failure, or those receiving high-dose or prolonged infusions of nitroprusside.[139] Doses greater than 2 mcg/kg/min and use in patients with liver or renal dysfunction are associated with toxic levels.[140] To prevent the development of toxicity, lower doses are recommended and the duration of infusion should be limited if possible. An early indicator of thiocyanate or cyanide toxicity is metabolic acidosis.[140] The use of thiocyanate levels should be limited to patients who require higher doses, long-term therapy, or have concomitant risk factors.

Propofol-related infusion syndrome (PRIS) is a constellation of life-threatening symptoms associated with severe metabolic acidosis, which can lead to fatal rhabdomyolysis or liver failure. In 2001, the FDA communicated a warning against off-label use of propofol for sedation in pediatric intensive care.[141,142] The FDA's concern came from reviewing data of a randomized, controlled clinical trial evaluating the safety and efficacy of propofol versus standard sedation regimens in pediatric intensive care patients. Approximately 10% of patients treated with propofol died, compared with 4% of children receiving standard treatment. More recently, Koriyama and colleagues evaluated 210 PICU patients who received propofol infusion rates of less than 4 mg/kg/hr for no longer than 24 hours. None of the patients developed PRIS using this strategy.[143] Although this and other large case series have reported the safe use of propofol without adverse effects, given the risks of mortality with PRIS, prolonged propofol infusions are not recommended in the pediatric ICU setting.[143,144]

Dermatologic

Drug-induced dermatologic reactions are the most common reported adverse events affecting 2% to 3% of all hospitalized patients. They include hypersensitivities, cutaneous eruptions or exacerbations, and severe cutaneous adverse reactions (SCARs). Drug-induced hypersensitivities describe both immunoglobulin-mediated allergic reactions and pseudoallergies. Urticaria, pruritus, angioedema, and facial flushing can occur with both types of hypersensitivity. Though their clinical presentation is similar, true allergic reactions require a sensitization period (approximately 5-21 days after the first dose) due to the activation of antibodies.[145] Allergic reactions are often associated with antimicrobials, antivirals, and aromatic anticonvulsants, such as phenobarbital and phenytoin. Coexisting conditions may also contribute the development of allergic reactions. For example, active infection with Epstein-Barr virus may increase the potential for a reaction to aminopenicillins.[146] Though commonly described as true allergies, dermatologic reactions to vancomycin, radiocontrast, aspirin, and ACE inhibitors are usually pseudoallergic.[145-147] Pseudoallergies include infusion-related reactions, skin flushing, and anaphylactoid reactions, which usually occur within minutes of administration. "Red man syndrome," facial and neck flushing associated with vancomycin, is an example of a pseudoallergy. As with other pseudoallergies, reducing the infusion

rate and premedicating with antihistamines are strategies to reduce the development of this adverse effect. Many medications are associated with hypersensitivities and pseudoallergy; therefore it is important to assess patients carefully when these types of reactions occur as a falsely labeled "allergy" may limit future treatment options.[145,148]

Maculopapular rashes are the most common type of drug-induced skin eruptions. Similar to hypersensitivity reactions, the rash usually develops 4 to 14 days after initiation of the causative medication. However, unlike urticaria, which is associated with IgE-mediated allergic reactions, maculopapular rashes are self-limiting and do not typically lead to more severe symptoms like angioedema and anaphylaxis. It is important to note that lesions located in the mucous membranes, palms, or soles of the feet are evident in approximately 90% of SCARs and may be a prelude to a more serious reaction.[149,150] After discontinuation of the suspected medication, most erythematous reactions can be treated with antihistamines and a low-dose steroid taper (if rash is diffuse).[151] Other types of drug-related skin eruptions include fixed drug eruptions (FDEs), acne, and psoriasis exacerbations. Fixed drug eruptions are small, defined lesions usually found on the face, lips, hands, feet, and genitalia.[152] Common medications associated with FDEs are acetaminophen, ibuprofen, and barbiturates.[152] Once discovered, the suspected medication should be discontinued. If rechallenge is necessary, the lesion will typically recur in the same location.[152] Acne, though not a serious adverse event, can lead to discomfort and possible issues of medication compliance. The location of drug-induced acne is similar to acne vulgaris (face, neck, and back); however, it is often distinguished by its papular presentation. Steroids, tacrolimus, lamotrigine, infliximab, epidermal growth factor receptor inhibitors, and cyclosporine have all been associated with acne.[153-155] Topical treatment with benzoyl peroxide products can help to treat drug-induced acne in order to avoid discontinuation of the causative agent. Similar to acne outbreaks, some medications can exacerbate psoriatic plaques in patients known to have this chronic condition (eg, NSAIDs, angiotensin-converting enzyme [ACE] inhibitors, and β-blockers) or cause psoriasis in those with no previous history (eg, growth hormone).[156] Topical corticosteroids may be helpful in treating exacerbations; however, in some instances the offending medication might need to be discontinued.

Serious cutaneous adverse reactions (SCARs) include drug rash with eosinophilia and systemic symptoms, Stevens-Johnson syndrome, toxic epidermal necrolysis, and warfarin-induced necrosis. Drug rash with eosinophilia and systemic symptoms (DRESS) is defined by a constellation of symptoms including high fever, symmetric maculopapular rash, and internal organ involvement. Often associated with anticonvulsants (eg, phenytoin and phenobarbital) and allopurinol, symptoms may take 3 to 8 weeks to develop after the initiation of the causative medication. Organ dysfunction may be severe and can lead to liver or kidney failure. Treatment includes supportive care and high-dose steroids.[157] In patients receiving allopurinol, it is beneficial to use doses less than 200 mg per day, adjust for renal dysfunction, and avoid concurrent use of thiazide diuretics.[158] Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are similar SCARs that are considered dermatologic emergencies. Often preceded by a viral-appearing prodrome, both conditions are associated with high fever and maculopapular skin eruptions, which then blister leading to epidermal necrosis and detachment. Though their presentations are similar, TEN is often considered a more severe presentation of SJS

due to the fact that patients with TEN develop epidermal detachment on greater than 30% of their body surface area (BSA) versus less than 10% of BSA in SJS.[159] Additionally, TEN is associated with acute renal failure, respiratory failure, and sepsis. Medications commonly known to cause SJS and TEN include allopurinol, lamotrigine, trimethoprim-sulfamethoxazole, and voriconazole.[159] Patients with SJS and TEN require admission to the ICU for supportive care including extensive wound care and surgical debridement.[159,160] In smaller studies, higher doses of intravenous immunoglobulin (IVIG) have been shown to decrease disease progression and improve outcomes.[161]

Warfarin-induced skin necrosis (WISN) is a severe cutaneous reaction that typically occurs within the first 10 days after the initiation of warfarin therapy. A dramatic drop in protein C, compared to other coagulation factors, creates a hypercoagulable state in which areas with higher amounts of adipose tissue can develop blistering plaques eventually leading to necrosis. Treatment includes discontinuation of warfarin, anticoagulation with heparin to prevent further microthrombi from developing, fresh-frozen plasma or protein C concentrate to restore protein C levels, and surgical debridement with or without skin grafting. Strategies to prevent WISN include initiation with lower doses of warfarin and bridging with heparin or low-molecular-weight heparin for at least 5 days when starting warfarin therapy.[43,162]

Drug-Drug Interactions

The pediatric intensive care physician is confronted daily with potentially hazardous drug-drug interactions in the critical care setting. A potential drug-drug interaction can be defined as "the possibility that one drug may alter the intensity of pharmacologic effects of another drug given concurrently. The net result may be enhanced or diminished effects of one or both of the drugs or the appearance of a new effect that is not seen with either drug alone."[118] Given the extent of polypharmacy occurrence, the potential risk is significant. Of the thousands of documented drug-drug interactions, only a small fraction is clinically significant.[163] The ability to differentiate between clinically significant and insignificant interactions requires an understanding of their mechanisms of action. In most cases, drug-drug interactions are predictable and preventable with appropriate dose modifications or avoidance of combinations.

The magnitude of drug-drug interactions is measured by the intensity of the response. Medications with narrow therapeutic indices are especially susceptible to drug-drug interactions, as small alterations in exposure can lead to large changes in response. Typically, drugs with large therapeutic indices are at minimal risk for clinically significant drug-drug interactions.

Drug-drug interactions can occur by three different mechanisms: pharmacokinetic, pharmacodynamic, and pharmaceutical. Pharmacokinetic drug-drug interactions can be defined as "interactions which affect a target drug through alterations in their absorption, distribution, metabolism, or excretion; the result may be an increase or decrease in the concentration of drug at the site of action."[118] Pharmacodynamic interactions are defined as interactions at a common receptor site or that have additive or inhibitory effects as a result of actions at different sites.[118] Pharmaceutical interactions or incompatibilities "occur when drugs interact in vitro so that one or

both are inactivated."[164]

The ability to distinguish significant drug-drug interactions in the critical care setting is vital to patient care. The following discussion emphasizes the mechanisms that underlie various drug-drug interactions and identifies clinically significant interactions among therapeutic classes.

Pharmacokinetic Drug-Drug Interactions

The most common and well-studied etiology of drug-drug interactions occurs through pharmacokinetic interactions. Pharmacokinetic interactions can occur throughout the entire pharmacologic spectrum and can potentially affect the absorption, distribution, metabolism, or elimination of the compound of interest. However, drug-drug interactions are only important when they impact the resulting drug exposure to such an extent that the patient experiences an alteration in the expected drug effect, either through a diminution of the drug's effect (when drug exposure is decreased) or through a predisposition to adverse effects (when drug exposure is increased). It is important to recognize that the dearth of pharmacokinetic information available for most drugs in children often makes recognition of drug-drug interactions difficult. However, a thorough understanding of the mechanisms behind these interactions can create an index of suspicion that is necessary to identify potential interactions clinically.

Interactions Affecting Drug Absorption (Enteral Absorption)

Several factors determine the rate and extent of oral absorption of drug products. Drug-drug interactions affecting enteral absorption occur through several mechanisms with a common end result: alteration of availability of the drug at its primary site of absorption. The most common mechanisms include adsorption or complexation of the target drug by other drugs or food, alterations in the ionization of the drug through pH changes, and perturbation of normal GI function (eg, motility, bacterial colonization, and mesenteric blood flow). In the critical care setting, adsorption and complex formation are the most likely causes of decreased enteral drug absorption. Commonly prescribed medications (eg, sucralfate and kaolin pectin) are implicated in causing decreased absorption of other drugs by adsorbing target drugs and rendering them unavailable for absorption across the GI barrier.[165-167] Food, especially enteral formula, is capable of causing adsorption of drugs. Phenytoin, levothyroxine, flecainide, and warfarin all have known interactions with enteral formulations.[168-170] Although less commonly prescribed in the pediatric setting, tetracycline and quinolone antibiotics have long been known to cause drug complexes with metallic cations such as iron and calcium, resulting in a decreased effect of both the supplement and the antibiotic.[171,172] If it is necessary to give these medications via the feeding tube to patients on continuous enteral feeding, a multidisciplinary team including providers, dietitians, and pharmacists should work together to develop an appropriate strategy.

Interactions Affecting Drug Distribution (Protein or Tissue Binding)

Due to the fact that the majority of drugs are bound to plasma proteins or tissue binding sites, the most commonly cited mechanisms for drug-drug interactions affecting distribution are those that involve protein or tissue binding. Many factors

affect protein or tissue binding including pH, temperature, renal function, and low serum albumin. Several examples exist in which one drug displaces an object drug through competitive inhibition at a protein or tissue binding site. However, in most cases, the impact of the drug-drug interaction is minimal. The amount of free (active) drug may increase temporarily, but the free level falls back to its previous equilibrium as the clearance of drug subsequently increases. Most cases of increased free drug concentrations secondary to protein binding displacement occur when the displacing drug also inhibits the metabolism or excretion of the displaced drug. For example, probenecid not only displaces bound ceftriaxone from albumin binding sites but also inhibits the active secretion of the drug in the kidney, resulting in increased ceftriaxone concentrations.[173] The clinical implications of this interaction are minimal because of the wide therapeutic index for ceftriaxone.

Alterations in Total Body Water

An important mechanism for drug-drug interactions affecting drug distribution that often is overlooked is an alteration of body fluid composition. Severe dehydration can be caused iatrogenically, either through fluid restriction or overzealous diuretic use. In these cases, drug concentrations can be increased several-fold, resulting in adverse effects. Conversely, the volume of distribution of drugs can be increased significantly by increasing total body water. This can have the effect of decreasing drug concentrations to subtherapeutic levels. Drugs that distribute primarily in total body water, such as aminoglycosides, are particularly susceptible to these types of effects.[174]

Interactions Affecting Drug Metabolism

The majority of clinically relevant drug-drug interactions can be linked to an alteration in drug metabolism. The two major pathways for drug metabolism in humans are the phase I oxidative pathway and the phase II conjugation reactions. Inhibition or induction of the phase I pathway is the most studied mechanism of drug-drug interactions, especially in relation to the cytochrome P-450 system of enzymes. Table 126.5 lists the drugs that affect cytochrome P-450 enzymes and those metabolized by the various clinically relevant isoforms. Evaluation of a drug's potential to affect the P-450 system is now an integral part of new drug development, and many older drugs have been studied extensively, such that these interactions are often predictable in adults. However, the relative lack of formal pediatric studies makes predicting the impact of a particular interaction difficult in a given child. Factors that must be considered include the state of maturation of the particular isoform and the presence of compensatory pathways. In general, it is reasonable to assume that a reaction that occurs in adults will also occur in children; therefore proper adjustments should be made if necessary.

TABLE 126.5

P-Glycoprotein and Cytochrome P-450 Substrates, Inhibitors, and Inducers

	Substrates		Inhibitors		Inducers	
Pgp[a]	Amiodarone Cimetidine Ciprofloxacin	Levofloxacin Lidocaine Methylprednisolone	Amiodarone Carvedilol Chlorpromazine	Nicardipine Nifedipine Ofloxacin	Amiodarone Cyclosporine Dexamethasone	Nic Nif Phe

[a]Several drugs are listed as both P-glycoprotein (Pgp) inhibitors and inducers because their effects on Pgp expression can be concentration or duration related.

One important consideration is the timing of drug-drug interactions secondary to P-450 enzyme inhibition or induction. In general, enzyme inhibition results from competitive inhibition at the enzyme binding site and therefore becomes clinically relevant as soon as the offending drug reaches sufficient concentrations in the liver. Consequently, upon discontinuation of the offending drug, enzyme inhibition abates as the drug concentration falls. Drugs with short half-lives have a relatively short offset of effect, whereas those with longer half-lives can cause significant effects for prolonged periods after discontinuation. In contrast, enzyme induction results from an increase in the amount of enzyme synthesized by hepatic cells. Thus there is a lag between the time an inducer is introduced and the onset of induction effect. As expected, the offset of effect also is somewhat prolonged.

Phase II reactions are rarely rate limiting, which makes their potential to be the cause of clinically significant drug-drug interactions low. However, the potential does exist for drugs to inhibit conjugation, thus impeding the conversion of object drugs to their inactive metabolites. A classic example is the interaction between high-dose ascorbic acid and acetaminophen. Ascorbic acid competitively inhibits the sulfation of acetaminophen, resulting in accumulation of the glucuronide metabolite.[175]

Interactions Affecting Drug Excretion

The primary means for the elimination of drugs or their metabolites is through renal excretion. The process of renal excretion involves three mechanisms: glomerular filtration (GFR), active tubular secretion, and tubular reabsorption. All three mechanisms can be affected by drug-drug interactions.

Alterations in GFR secondary to drug-drug interactions most often result from fluctuation in renal blood flow. Drugs that act to reduce renal blood flow, such as cyclosporine or NSAIDs, can reduce GFR and increase the blood concentration of drugs eliminated by this route.[32,176-179] Conversely, drugs that improve renal blood flow could increase GFR and decrease plasma concentrations of drugs eliminated through the kidneys. As its name implies, active tubular secretion is an active process during which drugs bind to receptors and are transported across the tubular cells to be excreted. Drugs that compete for these binding sites may inhibit the secretion of other drugs and increase concentrations. The two most commonly cited inhibitors of active tubular secretion are probenecid (inhibits the site for weak acids

such as penicillin) and cimetidine (inhibits the site for weak bases such as procainamide). These reactions are rarely of clinical significance; however, the probenecid-penicillin interaction has been used therapeutically to increase penicillin serum concentrations.[180-183] Tubular reabsorption is a passive process in which drugs are reabsorbed into the systemic circulation from the lumen of the distal tubules. As with enteral absorption, only un-ionized molecules are available for reabsorption. Therefore drugs that alter the pH of the urine have the potential to alter tubular reabsorption of other drugs. A common example is phenobarbital, which is a weakly acidic drug. In overdose situations, sodium bicarbonate is administered to alkalinize the urine in the hopes that phenobarbital will become more ionized in urine, resulting in reduced tubular reabsorption and more rapid excretion. It is important to note that the effectiveness of this practice is unclear.[184]

Interactions Affecting P-Glycoprotein Receptors

Research in the oncology field has led to the identification of an important drug transporter that is ubiquitous throughout the human body, namely, P-glycoprotein (Pgp). Pgp can be found in renal tubule cells, hepatic cells, the blood-brain barrier, and mucosal cells of the intestines, pancreas, and adrenal glands. Table 126.5 lists drugs that are inhibitors or substrates for Pgp. In general, Pgp is believed to serve a protective function by transporting molecules out of the body or, in the case of the blood-brain barrier, out of the CNS. This is manifested in the gut by Pgp-mediated secretion of molecules back to the intestinal lumen after absorption, in the kidney by active tubular secretion, in the liver by active secretion into the bile, and in the CNS by active removal of molecules out of the CNS. Drugs that inhibit Pgp are expected to increase the concentrations of substrates (either in plasma or the CNS). Clinicians should be aware when coadministering Pgp substrates or inhibitors and should consider dose adjustments or alternative treatments when administering drugs with narrow therapeutic windows.

Pharmacodynamic Drug-Drug Interactions

A pharmacodynamic drug-drug interaction (DDI) can be defined as the combination of two or more drugs with additive, synergistic, or antagonistic pharmacodynamic effects. Feinstein and colleagues reported that the epidemiology of pediatric drug-drug interactions is not clearly understood. Although this cohort study suggests the advancement with computerized physician order entry, standardized prescribing and review of drug-drug interactions upon ordering may impact the number of drug-drug interactions for pediatric patients. Additive pharmacodynamic interactions occur routinely when two or more drugs of the same class are given in combination, as in the case of antihypertensive medications or anticonvulsants. A synergistic interaction occurs when the combination of two drugs has an effect greater than the sum of their individual effects. One example of a clinically relevant synergistic interaction is the use of aminoglycosides in combination with β-lactam antibiotics. In theory, combining a cell-wall active agent (β-lactam antibiotic) with an agent that inhibits bacterial protein synthesis (aminoglycoside) can achieve a greater antibiotic effect than the sum of the two individual effects. Although difficult to prove clinically, in vitro and animal studies have validated this theory.[185-187] Most antagonistic drug-drug interactions are more appropriately defined as

pharmacokinetic interactions because they result from some alteration in drug concentrations, either in plasma or at the site of action. Antagonistic interactions that are truly pharmacodynamic in nature most often result from competitive inhibition at the receptor site for drug activity. Use of flumazenil to reverse benzodiazepine-induced sedation is an example of an antagonistic pharmacodynamic drug-drug interaction used clinically.[188-190]

Drug-Drug Interactions in Intravenous Admixtures

Parenteral administration of drug therapy poses a potential source of drug-drug interactions in the pediatric and neonatal intensive care units. Infusion of drugs with known incompatibilities could have serious consequences when administered to the patient. Introduction of a precipitate to venous circulation could produce adverse effects such as phlebitis and pulmonary embolism.[191] Factors influencing the need for coadministration of medications include a limited number of IV access sites, an extensive drug therapy regimen, time constraints, and the need to administer other lengthy infusions (eg, blood products).

Incompatibilities result from chemical reactions that may or may not be visible. Physical incompatibilities are easily identifiable because they illustrate any one of the following visual phenomena: precipitation, complexation, turbidity, color change, evolution of gas, or separation of the solution into distinct immiscible layers.[192] On the other hand, instability occurs when a mixture of drug solutions chemically reacts to yield a different species or degradation product, either of which could be pharmacologically inactive or even toxic. The rate at which these reactions occur adds another variable in determining whether or not two drug solutions can be infused together and for what duration. Generally, incompatibility is defined as a 10% decomposition of one or more components in an admixture in less than 24 hours.[192] Alterations in pH of the chemical environment, reduction-oxidation reactions, chelation, and “salting out,” which occurs when nonelectrolytes are exposed to strong electrolyte solutions, can lead to inactivation or visually ascertained incompatibilities such as precipitation.

Drug-Drug Interactions by Therapeutic Class

As opposed to many other classes of drugs, alterations in pharmacodynamics are the most common mechanism of cardiovascular drug-drug interactions. The potential for two drugs to act upon the same receptor subtype sets the stage for pharmacodynamic interactions, which can be antagonistic, additive, or synergistic in nature.

Cardiovascular Agents

Sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, dopamine, dobutamine, ephedrine, and isoproterenol) are particularly susceptible to pharmacodynamic drug-drug interactions. The extent and significance of these interactions depend on the selectivity of both the object drug and precipitant drug for adrenergic receptor types. β-adrenergic antagonists generally antagonize the cardiac and bronchodilating effects of the sympathomimetics.[193] However, propranolol and other nonspecific β-adrenergic antagonists (Table 126.6) may

enhance the vasoconstriction produced with epinephrine. As a result, the patient may experience hypertension and bradycardia.[71,72] Labetalol possesses both α_1-adrenergic and nonspecific β-adrenergic antagonistic activity, which produces an increase in diastolic blood pressure and a decrease in heart rate when given during an epinephrine infusion.[71,72] However, metoprolol and other β_1-cardioselective antagonists have minimal effects on the vasopressor response when given concomitantly with epinephrine.[71,72] Other classes of drugs can interact with the sympathomimetics as well. Linezolid, an antibiotic often reserved for drug-resistant methicillin-resistant *Staphylococcus aureus* (MRSA) infections, inhibits monoamine oxidase, which can increase sensitivity to vasopressor effects. When adding linezolid to vasopressor therapy, a reduction in dosing may be needed based on the hemodynamic response.[194] Antihistamines, such as diphenhydramine, inhibit tissue uptake of epinephrine and norepinephrine while increasing adrenoreceptor sensitivity to epinephrine.[193]

TABLE 126.6

β-Blocker Receptor Selectivity

	Intrinsic Sympathomimetic Activity (ISA)	Alpha-Blockade
Beta-1 Selective		
Metoprolol	None	None
Atenolol	None	None
Esmolol	None	None
Sotalol	None	None
Beta Nonselective		
Propranolol	None	None
Nadolol	None	None
Labetalol	Yes	Yes
Carvedilol	None	Yes

Adapted from Barres V, Taglialatela M. New advances in beta-blocker therapy in heart failure. Front Physiol. 2013;4:1-9.

General anesthetics, such as sevoflurane, and halogenated hydrocarbons, halothane, can increase cardiac irritability and sensitize the myocardium to the arrhythmogenic effects of sympathomimetics. Tachycardia and arrhythmias are reported with concurrent administrations.[193] Atropine also blocks reflex bradycardia produced by epinephrine, norepinephrine, and phenylephrine. This effect augments the vasopressor response to these medications.[193] Finally, case reports and animal studies have shown that concurrent administration of dopamine and intravenous phenytoin or fosphenytoin produces hypotension and bradycardia. Cardiovascular status should be monitored closely when these medications are given concomitantly.[71,72]

The pharmacologic effect of vasodilators, such as sodium nitroprusside, hydralazine, and diazoxide, are augmented by both β-adrenergic antagonists and diuretics. The decreased systemic vascular resistance and resultant reduction in mean arterial pressure provide stimuli for a compensatory increase in sympathetic nervous system activity. Normalization of blood pressure to the set point then is mediated by an increase in cardiac contractility, increased heart rate, and stimulation of the renin-angiotensin-aldosterone (RAA) pathway. β-Adrenergic antagonists prevent this sympathetic outflow and thereby enhance the vasodilator and resultant hypotensive response. The combination of certain vasodilators and sildenafil may

produce additive hypotensive effects. Studies have shown sildenafil to be effective in the treatment of pulmonary hypertension and chronic lung disease in pediatric and neonatal critical care.[195,196] The increased use of this medication, especially in cardiac patients, has necessitated heightened surveillance of potential interactions. Contact between sodium nitroprusside molecules and erythrocytes or the vascular wall generates nitric oxide. Nitric oxide subsequently stimulates the cyclic guanosine monophosphate (cGMP) second messenger system in vascular smooth muscle. The molecular process of increasing intracellular concentrations of cGMP translates to vasodilation and the resultant physiologic effect of reduced blood pressure. Sildenafil augments the response to cGMP through selective inhibition of type 5 phosphodiesterase, the enzyme that catalyzes degradation of cGMP. Therefore sildenafil can react similarly with other drugs, such as nitroglycerin and hydralazine, which also promote the generation of a nitric oxide. Sildenafil is also metabolized by the cytochrome P-450-3A4 enzymes, which can cause significant interaction potential with CYP3A4 inhibitors. Concentrations of sildenafil have been increased by as much as 182% when combined with erythromycin.[197] It is recommended that clinicians monitor patients closely for the increased hypotensive effects of sildenafil if concomitant administration of CYP3A4 inhibitors, such as macrolides, cimetidine, or azole antifungals, cannot be avoided.

The antiarrhythmic drugs amiodarone, disopyramide, and quinidine are substrates for the CYP3A4 isoform of the P-450 enzyme system. Plasma levels of these antiarrhythmics may increase and produce adverse effects when combined with CYP3A4 inhibitors such as the macrolide antibiotics, azole antifungals, and other miscellaneous inhibitors such as cyclosporine, certain calcium channel blockers (diltiazem and verapamil), and grapefruit juice. Conversely, plasma levels decrease when therapy is combined with drugs that are known enzyme inducers, which include phenobarbital, carbamazepine, phenytoin, oxcarbazepine, and rifampin. The antiarrhythmic drugs flecainide, mexiletine, and propafenone are substrates for CYP2D6. Concomitant therapy with enzyme inhibitors of CYP2D6, including amiodarone, cimetidine, diphenhydramine, fluoxetine, paroxetine, haloperidol, propafenone, and quinidine, could result in toxicity.[71,72]

As a substrate for Pgp, digoxin exhibits reduced renal and nonrenal clearance when a Pgp inhibitor is added to the drug regimen. Plasma levels of digoxin may increase 100% to 200%, demanding close monitoring for digoxin toxicity. Pgp inhibitors include amiodarone, clarithromycin, cyclosporine, diltiazem, erythromycin, ketoconazole, itraconazole, propafenone, quinidine, and verapamil.[71,72]

Pharmacodynamic interactions with drugs that modulate atrioventricular (AV) nodal conduction may produce clinically significant adverse effects, which can include heart block, bradycardia, and other arrhythmias. Concurrent therapies with antiarrhythmic agents, calcium channel blockers, and β-adrenergic antagonists should be monitored closely or even reevaluated.[198] Patients with severe electrolyte imbalances may be susceptible to digoxin toxicity. Hypokalemia, hypomagnesemia, and hypercalcemia are all conditions that may be drug induced. Therefore drugs may interact with digoxin in an indirect manner through alteration of electrolyte homeostasis. Loop diuretics, thiazide diuretics, amphotericin B, corticosteroids, laxatives, and sodium polystyrene sulfonate may all contribute to digoxin toxicity.[193,199,200]

Calcium channel antagonists have been implicated in several common pharmacokinetic drug-drug interactions involving the CYP3A substrates. Additionally, inhibitors of CYP3A can lead to significant interactions with calcium channel antagonists. These interactions enhance the development of lower diastolic blood pressure, higher heart rates, and other vasodilation-related side effects.[198] Inducers of CYP3A4 are implicated in the reduced efficacy of calcium antagonists.[198] Droperidol affects cardiac repolarization, prolongs the QT/QTc interval, and, when concurrently administered with calcium channel antagonists, increases the risk of QT/QTc prolongation, torsades de pointes, and cardiac arrest.[201] Concomitant administration of fentanyl and nicardipine can result in severe hypotension.[202] Awareness and monitoring of potential drug-drug interactions are necessary when administering calcium channel antagonists.

β-Adrenergic antagonists (β-blockers) are associated with a variety of pharmacodynamic and pharmacokinetic drug-drug interactions as well. Concomitant use of a β-adrenergic antagonist and verapamil or diltiazem can result in additive negative inotropic effects and can potentiate conduction abnormalities.[203,204] Abrupt withdrawal of clonidine when concomitantly used with a β-blocker can exaggerate rebound hypertension symptoms associated with clonidine withdrawal.[205,206] The probable mechanism of this interaction is unopposed α-adrenergic agonism. Use of amiodarone with β-adrenergic antagonists potentates bradycardia, sinus arrest, and AV block.[202]

Angiotensin-converting enzyme inhibitors (ACEIs) have been implicated in a variety of drug-drug interactions. Electrolyte disturbances are a major source of complications with these drug-drug interactions. Potassium-sparing diuretics, such as spironolactone and eplerenone, in combination with ACEIs increase serum potassium levels.[207] Nesiritide, a medication often used to treat decompensated heart failure, can suppress the renin-angiotensin-aldosterone system; therefore it is important to monitor patients for severe hypotension when concurrently administering this medication with ACEIs.[208]

Anticonvulsant Medications

The antiepileptics constitute a drug class that has the potential to be involved in a large array of drug-drug interactions. These interactions are mainly pharmacokinetic in nature and usually involve induction, inhibition, or competition among substrates for various isoforms of the cytochrome P-450 enzyme system. Fortunately, these drugs typically are monitored using blood concentrations, and appropriate therapeutic drug monitoring can aid in the avoidance of adverse events secondary to drug-drug interactions. Table 126.5 lists the isoforms for which the various antiepileptics are substrates, inducers, or inhibitors.

In the intensive care unit setting, phenytoin is generally administered intravenously in the form of the water-soluble prodrug fosphenytoin. Phosphatases in red blood cells and the liver catalyze the conversion of fosphenytoin to its active form phenytoin. Fosphenytoin has a serum half-life of 8 to 15 minutes.[209] Once fosphenytoin is converted to phenytoin, it is susceptible to all of the potential drug-drug interactions that affect orally administered phenytoin. Approximately 95% of phenytoin is metabolized in the liver by the CYP2C9/10 and CYP2C19 isoforms of the cytochrome P-450 enzyme system to produce the inactive metabolite parahydroxyphenylhydantoin.[209] The CYP2C9/10 isoform is the main pathway of

metabolism for this drug. Phenytoin metabolism is reduced and plasma levels increased via competition with other drugs that are substrates for CYP2C9 and CYP2C19, such as amiodarone, fluconazole, valproic acid, omeprazole, and fluoxetine. Conversely, phenytoin may competitively inhibit the metabolism of these drugs. Drugs that inhibit CYP2C9 reduce clearance of phenytoin and consequently increase plasma concentrations.[210] Examples include fluconazole, ketoconazole, cotrimoxazole, amiodarone, and valproate. Omeprazole, cimetidine, and fluoxetine are inhibitors of CYP2C19 and thus can increase phenytoin plasma concentrations.[210] In addition to serving as a substrate to CYP2C9/10 and CYP2C19, phenytoin can also induce their activity. Moreover, phenytoin induces CYP3A4 and uridine diphosphate glucuronosyltransferase (UGT) activity.[209] It may take 1 to 2 weeks for maximum induction of these enzymes when phenytoin therapy is started and, conversely, the same amount of time for de-induction once the drug is discontinued.[210] Phenytoin exhibits a high degree of protein binding (≥90%) to serum proteins, mainly albumin, so displacement from its binding sites may produce clinically significant changes in free phenytoin concentration.[209] The free fraction is the pharmacologically active portion of the total phenytoin concentration in plasma. Populations in whom increased proportion of free drug may be found include neonates, patients with uremia, hyperbilirubinemia, or hypoalbuminemia, as well as patients taking concurrent anionic drugs.[209,211,212] During the hospital course of critically ill children who experienced traumatic head injuries, protein binding and phenytoin metabolism can be altered.[213] The free fraction of phenytoin may increase over time in patients with acute head injury.[214] Such a clinical condition makes this particular population of patients especially susceptible to potential protein displacement interactions with other highly protein-bound drugs, such as valproic acid. The potential clinical significance of this interaction is an increased risk for phenytoin toxicity.

Phenobarbital is a substrate for CYP2C9, CYP2C19, and CYP2E1. The CYP2C19 isoform serves as the primary pathway for metabolism.[209] Phenobarbital is converted to 5-p-hydroxyphenyl-5-ethyl-barbituric acid, an inactive species, and further conjugated with glucuronic acid or sulfuric acid for excretion in urine.[209] Phenobarbital has the potential to induce CYP2C9 and CYP3A4 enzymes.[215] The time frame for induction and de-induction of the P-450 enzyme system depends on phenobarbital's half-life, with induction beginning 1 week after initiation of phenobarbital therapy and de-induction beginning 1 week after phenobarbital is discontinued. Maximum induction occurs in approximately 2 to 3 weeks. Phenobarbital also induces UGT.[210] Addition of phenobarbital or phenytoin to a regimen of methadone, which may be used in the intensive care unit for the purpose of weaning from long-term opiate sedation, may present a potential for significant drug-drug interaction. Induction of CYP2C9 and CYP3A4 leads to increased clearance of methadone, increasing the possibility of methadone withdrawal. In transplant patients, phenobarbital may reduce cyclosporine concentrations, which may lead to concerns regarding adequate immunosuppression. Another significant drug interaction involves the abrupt withdrawal of phenobarbital in a patient maintained on both phenobarbital and warfarin. In such a scenario, blood levels of warfarin may increase and lead to increased risk of bleeding. During maintenance of such a regimen, phenobarbital induces the same enzymes responsible for warfarin metabolism. As a result, warfarin dosing is adjusted based on phenobarbital-

mediated inhibition of the hypoprothrombinemia response.

Oxcarbazepine undergoes extensive metabolism through the liver to an active metabolite, 10-monohydroxy (MHD). The main pharmacologic properties of oxcarbazepine are due to its active metabolite MHD. Oxcarbazepine is a weak inhibitor of CYP2C19 and strong inducer of CYP3A4/5 isoforms. When oral contraceptives, dihydropyridine calcium antagonists, and cyclosporine are given concomitantly with oxcarbazepine, decreased drug levels were shown, due to the induction of CYP3A4/5 isoforms.[216]

The isoforms of the P-450 enzyme system that metabolize valproic acid include CYP2C9 and CYP2C19, both of which represent minor pathways. The main route of metabolism for valproic acid involves glucuronidation by UGT and β-oxidation.[209] Valproate inhibits drugs that are metabolized by CYP2C9, such as phenytoin and phenobarbital. In addition to being a substrate for UGT, valproic acid inhibits drugs that are metabolized by this enzyme, such as lorazepam and lamotrigine. Valproic acid also exhibits a high degree of protein binding to plasma albumin (90%), making protein displacement interactions likely with other highly protein-bound drugs.[209]

The main pathway for metabolism of lamotrigine is UGT-mediated glucuronidation. Lamotrigine is capable of inducing its own metabolism, with maximum autoinduction observed within 2 weeks. Autoinduction typically results in a 17% reduction in plasma blood levels.[217] Through their action on UGT, carbamazepine, phenytoin, and phenobarbital reduce plasma concentrations of lamotrigine when given concomitantly. Lamotrigine, on the other hand, reduces valproic acid plasma levels when added to a regimen containing valproic acid. Concentrations may be reduced by as much as 25% in the course of a few weeks.[209]

Antiinfective and Antimicrobial Agents

Antimicrobial agents are commonly used in the intensive care unit to treat patients with serious infections. Many drug-drug interactions involve antimicrobial agents; however, some are not clinically significant.[101] Complexation of fluoroquinolones (ciprofloxacin, levofloxacin) to multivalent cations (aluminum, calcium, magnesium, and iron) due to binding within their chemical structures is an example of an interaction that can be easily managed by administering the drugs at separate times.[218,219]

Macrolide antibiotics, on the other hand, are associated with many drug-drug interactions that can be of clinical importance. Erythromycin may cause interactions through inhibition of the CYP3A4 enzyme, which can increase serum levels of warfarin, cyclosporine, midazolam, and tacrolimus.[220,221] Clarithromycin also inhibits cytochrome P-450 enzymes and may increase the serum levels of carbamazepine, caffeine, cyclosporine, warfarin, valproate, and midazolam.[220,221] Azithromycin is an azalide (macrolide subclass) that does not demonstrate cytochrome P-450 complexation, so it has less drug interaction potential. No major drug-drug interactions have been shown with azithromycin and carbamazepine, theophylline, or midazolam.[220] Interactions with cyclosporine and warfarin are limited to case reports; therefore monitoring of serum levels and international normalized ratio (INR), respectively, is prudent when using this combination.[222]

Carbapenems are commonly used in the intensive care unit for treatment of gram-negative sepsis. Though not commonly associated with significant drug-drug interactions, concurrent use of carbapenems with valproic acid and its derivatives

can cause a significant and sudden decrease of valproate serum concentrations.[223] The effect is most significant with meropenem where a decrease of up to 90% in valproic acid levels can be observed.[224,225] In patients who need valproic acid for primary prevention of seizures, use of carbapenems is discouraged. However, if no substitute is available, the addition of a second antiepileptic agent should be considered to control seizures and prophylaxis.

Rifampin is a cytochrome P-450 enzyme inducer that is involved in many drug-drug interactions. Rifampin may decrease serum concentrations of chloramphenicol, isoniazid, amiodarone, cyclosporine, prednisolone, and warfarin.[226,227] These interactions often complicate multidrug regimens for treatment of active tuberculosis or nontuberculous mycobacteria.

Antifungal agents are used in the critical care setting for treatment and prophylaxis of systemic mycoses. Azole derivatives inhibit sterol 14-α-demethylase, which is a hepatic microsomal cytochrome P-450–dependent system. Unfortunately, this mechanism results in significant drug-drug interactions. Azole antifungals are known inhibitors of cytochrome P-450 isoenzymes, although the specific CYP isoforms and potency of inhibition vary among agents.[110,228,229] Table 126.5 describes cytochrome P-450 isoforms inhibited by the azole antifungals. Clinically significant interactions with azoles occur most frequently with agents that have narrow therapeutic windows and are metabolized by cytochrome P-450 enzymes. Additionally, significant interactions can occur when azole derivatives are administered with CYP3A substrates such as midazolam,[228-230] tacrolimus,[231,232] sirolimus, cyclosporine,[233] nifedipine,[199] felodipine,[199,234] diltiazem,[232] and alfentanil.[235]

Benzodiazepines that rely on the CYP3A4 enzyme for biotransformation are predisposed to drug-drug interactions with CYP3A inhibitors. The benzodiazepines most prone to interactions are alprazolam, diazepam, midazolam, and triazolam.[229,236,237] Ketoconazole, a potent inhibitor of CYP3A, increases the area under the concentration–time curve (AUC) of oral midazolam by 16-fold.[229,234,238-241] Whenever azole antifungals are administered with midazolam, patients must be monitored for increased response to midazolam, and dose alteration or discontinuation of therapy should be considered. Diazepam metabolism is mediated by CYP3A and CYP2C19 and is also prone to interactions with azole derivatives.[242] Fluconazole and voriconazole are inhibitors of CYP3A, CYP2C9, and CYP2C19 and have the potential to cause drug interactions with compounds that are metabolized via this pathway, including diazepam, which is metabolized by CYP3A4 and CYP2C19.

Warfarin is a racemic mixture compound for which most pharmacodynamic activity occurs with the S-isomer, whose metabolism is also dependent on CYP2C9, which is inhibited by fluconazole and voriconazole.[232,243] This interaction is significant, and appropriate dosage modifications or alteration of therapeutic agents must be considered. The calcium channel antagonist class is metabolized by CYP3A isoenzymes and has the potential for interactions with azole derivatives.[234] Drug levels of azole antifungals, especially itraconazole, voriconazole, and posaconazole, may be rendered undetectable when used in conjunction with strong P-450 enzyme inducers like rifampin.[244,245] Alternative antifungal agents should be considered in situations where rifampin cannot be discontinued.

In addition to being CYP3A inhibitors, ketoconazole and itraconazole are substrates and inhibitors of Pgp.[246,247] Drug-drug interactions mediated via Pgp

typically are important determinants of bioavailability, liver metabolism, and kidney excretion.[248,249] Diltiazem, verapamil, cyclosporine, and tacrolimus are dual CYP3A and Pgp substrates.[250] Clearance of digoxin, a Pgp substrate, is decreased with coadministration of itraconazole due to impaired renal tubular secretion via inhibition of Pgp, resulting in an increase in digoxin trough concentration.[199] Oral absorption of itraconazole and posaconazole is pH dependent and may result in a clinically significant decrease in therapeutic efficacy if these agents are used concurrently with proton-pump inhibitors or H_2 antagonists. This interaction is more pronounced with the liquid formulations of the medications. Echinocandins are a relatively new class of antifungal that are increasingly used in the treatment of fungal infections due to its relatively safe side effect profile and lack of cytochrome P-450 and P-glycoprotein mediated drug interactions. Among the three currently available echinocandins—micafungin, caspofungin, and anidulafungin—caspofungin is most commonly associated with drug interactions due to the role of hepatic transporter organic anion-transporting polypeptide (OATP)-1B1 in the uptake of caspofungin. Rifampin, an OATP inhibitor, can reduce caspofungin levels, and therefore an increased caspofungin dose is recommended when coadministered with rifampin.[251]

Anesthetic Agents and Sedatives

Several agents are used for anesthesia and sedation in the pediatric critical care setting. Many of these drugs have clinically significant drug-drug interactions. The ability to recognize potential drug-drug interactions related to the use of anesthetic agents or sedatives in the pediatric critical care setting requires a fundamental understanding of the agent's clinical pharmacology. Benzodiazepines are a class of sedatives that are particularly susceptible to drug-drug interactions because of their route of biotransformation.[229,252,253] CYP3A4 plays a major role in the metabolism of midazolam, triazolam, and alprazolam, and caution should be exercised when combining these agents with CYP3A modulators.[254-256] As mentioned previously, concomitant use of systemic antifungals and benzodiazepines results in a known clinically significant drug-drug interaction, caused by azole antifungals inhibiting the CYP3A isoenzyme.[252] Midazolam, a short-acting benzodiazepine used in the pediatric critical care setting, is almost exclusively metabolized via the CYP3A pathway. Interactions are most prominent with oral midazolam therapy because of the role of intestinal metabolism.[229,230,252] However, significantly increased plasma levels have been observed when intravenous midazolam is administered with fluconazole.[229,230,252] Additionally, clarithromycin and erythromycin have been proved to significantly decrease systemic clearance of intravenous and oral midazolam.[230,257,258] Azithromycin, another macrolide, does not appear to increase plasma concentrations of oral midazolam.[240] Propofol has been shown to decrease the clearance of midazolam by 37%, possibly by competitive inhibition of CYP3A4.[259,239] Concomitant administration of verapamil or diltiazem with oral midazolam is associated with dramatic increases in AUC and the maximum concentration (C_{max}).[239] Inducers of CYP3A can drastically decrease plasma concentrations of midazolam. Rifampin, a potent inducer of CYP3A and Pgp expression in the gut mucosa, can cause dramatic decreases in plasma concentrations of oral midazolam.[239,260] Other inducers of CYP3A enzymes implicated in significant

interactions with midazolam are carbamazepine and phenytoin.[255] Diazepam, a benzodiazepine with long-acting metabolites, is prone to drug-drug interactions with inhibitors or inducers of CYP2C19 or 3A4. Due to the fact that the primary route of metabolism for lorazepam is through glucuronidation, this agent is associated with fewer potential pharmacokinetic drug-drug interactions.[236]

The potential for pharmacodynamic drug-drug interactions also exists with sedative agents. Concomitant use of barbiturates and benzodiazepines causes additive respiratory and CNS depression. This is mediated by allosteric conformational changes at the γ-aminobutyric acid (GABA) site, which regulates the opening of chloride channels, causing the neurons to become hyperpolarized and resistant to excitation.[261] The dosage of midazolam and other benzodiazepines often is reduced by 30% to 50% when they are administered concomitantly with opioid analgesics.[262] Flumazenil competitively inhibits the activity of benzodiazepines at its recognition site on the GABA-benzodiazepine receptor complex; however, it does not reverse the CNS effects of GABA-mimetic agents such as barbiturates, propofol, and other general anesthetics.[263]

Clonidine, an α_2-adrenergic agonist agent with sedative properties, reduces the induction concentrations needed for loss of consciousness when using propofol.[264] Propofol can inhibit the clearance of alfentanil and act synergistically with opioids.[265,266] Caution should be exercised when using propofol in combination with drugs that lower seizure threshold, such as meperidine and enflurane.[267]

Neuromuscular blocking agents have significant drug-drug interactions.[268] Concomitant use of intravenous antibiotics such as aminoglycosides or clindamycin has the potential to intensify neuromuscular blockade produced by neuromuscular blocking agents.[268] Phenytoin has been shown to increase pancuronium requirements. Additionally, inhalation anesthetic agents can also potentiate neuromuscular blockade.[268]

Analgesic Agents

A variety of agents are used for analgesia in the pediatric critical care setting. Patients receiving opioid analgesia are particularly susceptible to drug-drug interactions. Whenever an opiate agonist is administered with an agent that has CNS depressant effects, augmented effects or toxicity is possible. Therefore vigilance in monitoring for drug-drug interactions is necessary when administering these agents to help ensure that safe and effective analgesia is achieved. Analgesic pharmacokinetic drug-drug interactions can mediate clinically relevant effects. CYP3A is involved in the metabolism of methadone and alfentanil.[258] Methadone metabolism is induced by rifampin and results in enhanced clearance of methadone.[269,270] One study of adults demonstrated an approximately fourfold increase in methadone clearance when administered with rifampin.[271] This effect could provoke withdrawal symptoms in patients receiving methadone.[272] Phenobarbital, phenytoin, carbamazepine, nevirapine, and efavirenz have the potential to decrease methadone blood concentrations as well.[273,274] Rifampin significantly lowers alfentanil plasma concentrations by the same mechanism.[258] On the other hand, inhibition of CYP3A can result in increased plasma levels of methadone.[269] For example, fluconazole inhibits metabolism of methadone and alfentanil.[235,269] Fluconazole decreased the clearance of alfentanil approximately 58%

following intravenous fluconazole administration in healthy adults.[235]

Pharmacodynamic drug-drug interactions can result in synergic effects or antagonism. When a pure opiate agonist, a partial agonist, or an antagonist, is used in combination, there is a risk for decreased clinical effects. For example, when morphine (a pure μ agonist) and nalbuphine (a partial agonist/antagonist) are used in combination, it can decrease the opiate effect. This can have profound effects on analgesia and result in withdrawal symptoms for patients on long-term analgesia therapy.[275,276] Analgesic opioid therapy is associated with several side effects that can be heightened by drug-drug interactions such as respiratory depression, hypotension, decreased GI motility, nausea, and vomiting. Use of a pure opioid antagonist, such as naloxone, is needed to reverse undesirable effects. Most clinically significant drug-drug interactions associated with analgesics are pharmacodynamic in origin.

Anticoagulants

Warfarin is involved in a multitude of drug-drug interactions through a variety of mechanisms, including alterations in protein binding, effects of hepatic metabolism by the cytochrome P-450 system, disruption of bacterial flora in the GI tract, and changes in the clotting cascade (Table 126.7). Aspirin, chloral hydrate, ibuprofen, and sulfamethoxazole can displace warfarin from protein binding sites, increasing free fraction of warfarin available and hence augmenting anticoagulation. Warfarin metabolism may be inhibited by amiodarone, sulfamethoxazole, metronidazole, azole antifungals, macrolide and quinolone antibiotics, and isoniazid, thereby decreasing the effect.[276] Phenobarbital, rifampin, and phenytoin can induce the metabolism of warfarin and decrease its effect dramatically. In fact, concurrent administration of warfarin and rifampin is strongly discouraged, especially in high-risk patients like those with mechanical mitral valves. Most antibiotics have the potential to decrease synthesis of vitamin K–dependent clotting factors and potentiate warfarin's effect.[276,277] Other medications including NSAIDs and antiplatelet medications can exacerbate the adverse effects of warfarin by directly affecting the clotting cascade. Phytonadione (vitamin K) antagonizes the anticoagulant effect of warfarin.[215,277a] Careful monitoring of bleeding and coagulation parameters (prothrombin time and INR) can help prevent serious adverse drug reactions. Many drug-drug interactions can occur when initiating warfarin therapy or when adding other medications to existing warfarin therapy. It is recommended that clinicians use adjusted starting doses of warfarin when initiating therapy while patients are receiving medications with the potential for interaction.

TABLE 126.7

Medication Interactions That Modify the Anticoagulant Effect of Warfarin

Increased INR	Decreased INR	Increased Risk of Bleeding	Increased Risk of Thrombosis
CYP-450 Inhibition via 2C9 (unless otherwise noted) Antidepressants Fluvoxamine	**CYP-450 Induction via 2C9** (unless otherwise noted) Carbamazepine Phenobarbital	**Alterations in Platelet Function** Antiplatelet Agents Aspirin Cimetidine Clopidogrel	**Alterations in Warfarin Metabolism or Absorption** Cholestyramine Griseofulvin Nafcillin Ribavirin

Sertraline	Phenytoin	Fish oil	Sucralfate
Antiinfectives	Rifampin	Ticlopidine	**Prothrombotic**
Azole Antifungals (2C9/3A4)		Antifibrinolytics	Estrogens
Cotrimoxazole		Alteplase	OCPs
Fluoroquinolones (1A2/3A4)		Streptokinase	Phytonadione
Isoniazid		Urokinase	Total parenteral nutrition
Macrolides		NSAIDs	
Metronidazole		Aspirin	
Miconazole		Ibuprofen	
Cardiovascular Drugs		Indomethacin	
Amiodarone		Ketorolac	
Fluvastatin		SSRIs	
Gemfibrozil		Citalopram	
Lovastatin		Sertraline	
Simvastatin		**Reduced Vitamin K Production**	
		Antiinfectives (oral)	
		Omeprazole	
		Miscellaneous	
		Corticosteroids	
		Levothyroxine	
		Propranolol	

INR, international normalized ratio; *NSAIDs*, nonsteroidal antiinflammatory drugs; *OCP*, oral contraceptive pills; *SSRI*, selective serotonin reuptake inhibitor.

Modified from Hansten PD. Oral anticoagulants and drugs which alter thyroid function. Drug Intell Clin Pharm. 1980;14:331-334; Liu A, Stumpo C. Warfarin drug interactions among older adults. Geriatrics Aging. 2007;10:643-646; Holbrook AM, Pereira JA, Labris R, et al. Systematic overview of warfarin and its drug and food interactions. Arch Intern Med. 2005;165:1095–1106.

Heparin has the ability to interact with other agents, which can increase the risk of bleeding or thrombosis by altering heparin's effect. Common interactions include oral anticoagulants and platelet inhibitors (eg, aspirin, dextran, ibuprofen, and other agents that interfere with platelet aggregation). Heparin's effectiveness can also be altered by the administration of additional clotting factors found in fresh frozen plasma and antithrombin III. Antifibrinolytic agents, which can enhance the anticoagulant effects of heparin, have become one of the primary treatments for larger arterial or intraatrial clots. Though concomitant anticoagulation with heparin is often indicated with antifibrinolytic agents and blood products, it is important to adjust heparin infusion rates and monitor the patient's response when combining these medications. Enoxaparin and other low-molecular-weight heparins have similar interactions with medications independently associated with an increased risk of bleeding as mentioned earlier.[278] Additionally, medications that adversely affect renal clearance can prolong the elimination half-life of enoxaparin and increase the risk of adverse effects.[278]

There are many newer oral anticoagulants on the market, mostly used in adults, that are currently being studied in pediatric patients. Limited data are available for dosing and monitoring; however, as they may become more prevalent in this population it is important to mention possible drug-drug interactions. Dabigatran, an enteral direct thrombin inhibitor similar to warfarin, and the oral anti-factor Xa inhibitors rivaroxaban, apixaban, and edoxaban have interactions with Pgp inhibitors like rifampin (see Table 126.5). All but edoxaban and dabigatran can interact with strong CYP3A4 inhibitors such as azole antifungals and macrolides (see Table 126.5). Additionally, dabigatran may interact with certain proton pump inhibitors. Dose reduction or modification of medication therapy may be required. As with other anticoagulants, close monitoring is required when using with antiplatelet agents or other medications noted to increase the risk of bleeding.[279,280]

Immunosuppressive Agents

Most immunosuppressive agents possess narrow therapeutic indices and therefore require therapeutic drug monitoring.[281,282] As a result, a sophisticated knowledge of clinical pharmacology is required to evaluate the clinical relevance of potential drug-drug interactions involving these drugs. Drug-drug interactions most commonly encountered with immunosuppressive drug therapy revolve around the inhibition or induction of the CYP3A enzymes. Cyclosporine, tacrolimus, prednisone, sirolimus, and everolimus are all CYP3A substrates and are most prone to these types of pharmacokinetic drug-drug interactions.[283,284] Interestingly, known CYP3A inhibitors, such as ketoconazole, have been used intentionally to maintain therapeutic levels in patients with high presystemic metabolism of cyclosporine.[285] Medications that inhibit CYP3A metabolism should be used with caution in patients taking cyclosporine, tacrolimus, sirolimus, or everolimus; however, if concomitant use cannot be avoided, dosing adjustments of immunosuppressive therapy may be required. Table 126.5 provides a list of medications that are CYP3A4 enzyme inhibitors. Concomitant administration of sirolimus or everolimus with cyclosporine increases sirolimus and everolimus exposure, likely due to shared CYP3A and Pgp metabolic pathways.[286,287] Several drugs can induce the metabolism of cyclosporine, tacrolimus, sirolimus, everolimus, and prednisone. Rifampin causes induction of CYP3A and Pgp, leading to clinically significant decreases in cyclosporine and tacrolimus plasma concentrations.[288,289] Although not considered to have a narrow therapeutic index, mycophenolate serum concentrations are affected by concurrent administration with cyclosporine. Cyclosporine decreases enterohepatic recirculation of mycophenolic acid, necessitating higher mycophenolate doses to achieve serum concentrations equivalent to that of the drug given alone or with tacrolimus.[290] This interaction may be overcome by using enteric-coated mycophenolic acid formulations.[291]

Azathioprine, an older immunosuppressant, is a prodrug of mercaptopurine, and its biotransformation is dependent on the thiopurine-S-methyltransferase (TPMT) enzyme, xanthine oxidase, and inosine monophosphate dehydrogenase (IMPDH). There are genetic polymorphisms of the TPMT enzyme that may predispose heterozygous and homozygous carriers of the gene to increased bone marrow toxicities with increased levels of the cytotoxic thioguanine (TGN) metabolite.[292] Concurrent use of allopurinol, a xanthine oxidase inhibitor, can increase systemic mercaptopurine exposure and toxicity, therefore a dose reduction of 65% to 75% is recommended to decrease risk of toxicity.[293]

Pulmonary and Respiratory Medications

β_2-Adrenergic agonists (eg, albuterol, levalbuterol, and terbutaline) are useful agents for treatment of asthma. Drug-drug interactions can occur when β_2-adrenergic agonists are used in combination with β_1-adrenergic antagonists, especially the nonselective antagonists. A possible decreased β_2 effect could precipitate asthma symptoms. The nonselective antagonists include propranolol, nadolol, and labetalol (see Table 126.6). Agents such as atenolol, esmolol, and metoprolol are relatively selective for β_1 receptors at therapeutic doses and are considered safer for use in combination with β_2-adrenergic agonists. However, these agents may lose their

selectivity at higher doses. One potential side effect of the β_2-adrenergic agonists is hypokalemia, which can be enhanced with concurrent use of loop and thiazide diuretics. Monitoring of potassium levels is recommended when these agents are used together.[215,293a]

Antineoplastic Agents

The majority of drug-drug interactions in patients receiving chemotherapy involve the cytochrome P-450 enzyme system. Potential interactions can be identified by pinpointing the substrates for the various isoenzymes of the mixed function oxidases among the antineoplastic agents. For example, the vinca alkaloids and many of the tyrosine kinase inhibitors are substrates for CYP3A4. Known inhibitors and inducers of CYP3A4 increase and decrease plasma levels, respectively. Toxicities are more likely when these agents are administered with classic CYP3A4 inhibitors such as the azole antifungals, macrolide antibiotics, calcium channel blockers (eg, diltiazem and verapamil), quinupristin/dalfopristin, and cyclosporine. The azole antifungals modulate the metabolism of cyclophosphamide, increasing overall parent drug and metabolite exposure. Fluconazole increases cyclophosphamide AUC by inhibiting CYP2C9 metabolism that leads to formation of the toxic metabolite acrolein, in effect reducing potential adverse drug effects.[294] However, the inhibition of the CYP3A4 metabolic pathway by itraconazole increases formation of the precursor to the acrolein metabolite, increasing toxicity risk.[295] Antiepileptic drugs that are known inducers of the cytochrome P-450 enzyme system may contribute to therapeutic failure with chemotherapeutic agents. In one study of pediatric patients with high-grade glioma, the presence of enzyme-inducing anticonvulsants increased irinotecan clearance.[296]

Multiple drug resistance in cancer cells has been attributed to the expression of a Pgp efflux transmembrane transport protein.[297] Agents that modulate the activity of Pgp currently may provide a drug interaction that favorably increases the efficacy of antineoplastic agents.[298] Coadministration of etoposide and cyclosporine, for example, elevates the mean AUC of etoposide. Etoposide is a CYP3A4 substrate, whereas cyclosporine is both a CYP3A4 and Pgp inhibitor.[299] Inhibitors of the efflux pump, Pgp, increase the cytotoxicity of the vinca alkaloids, anthracyclines, epipodophyllotoxins, and taxanes.[300] Itraconazole, clarithromycin, verapamil, and cyclosporine are known to inhibit Pgp as well.[71,72] Currently, attempts to utilize the increased toxicity associated with greater drug exposure due to Pgp inhibition have limited clinical application of these therapies.[71,72,298]

Colony-stimulating factors are often used to treat the ensuing neutropenia that accompanies cancer chemotherapy. Patients with lymphomas undergoing their first cycle of vincristine and receiving treatment with filgrastim or sargramostim are at risk for developing severe atypical neuropathy. This neuropathy has been described as a severe, sharp, burning pain in the feet and appears to occur more commonly in lymphoma patients receiving this combination than in patients receiving vincristine alone.[301] The mechanism of action of this interaction is unclear.

Methotrexate elimination occurs in the kidneys via filtration and active secretion. The process of tubular secretion requires a carrier, which is a saturable process. Competition among other drugs for secretion may reduce the clearance of methotrexate, which may lead to toxicity. Concurrent administration of

methotrexate with any of the penicillins has demonstrated this interaction.[302-304] The NSAIDs, aspirin, and other salicylates all increase the likelihood of methotrexate toxicity by this same mechanism.[30,305-309] Inhibition of renal prostaglandin synthesis and the resultant reduction in renal perfusion also contribute to renal toxicities seen with methotrexate because methotrexate can persist in renal tissue for weeks.[193] Proton pump inhibitors also create interactions with methotrexate due to effects on renal elimination. By inhibiting the transmembrane H^+/K^+-ATPase pump, they may decrease active secretion of methotrexate.[310] The antineoplastic activity of methotrexate stems from its inhibition of dihydrofolate reductase, the enzyme that catalyzes the reduction of folic acid to tetrahydrofolic acid. In turn, tetrahydrofolic acid serves as a building block for purine and DNA synthesis. The clinician should be aware of other drugs that act along this pathway, specifically cotrimoxazole, as these agents may contribute to the toxicities associated with methotrexate therapy.[193,311]

CHAPTER 127

Principles of Toxin Assessment and Screening

Alan D. Woolf

PEARLS

- Some toxins (eg, acetaminophen, *Amanita* mushroom poisoning, valproic acid, sulfonylureas) are notable for the delay from time of ingestion to onset of symptoms. Others with a long duration of action, such as methadone or naltrexone, can have symptom recurrence hours after an apparent good response to an antidote.
- Intensivists can often predict the severity of poisoning by noting the tempo of progression of a patient's signs and symptoms of toxicity.
- Clinicians must assess the intoxicated or comatose patient for the possibility of secondary trauma, such as fractures, intracranial bleeding, sexual abuse, rape, or internal injuries.

Despite progress in preventive measures, poisonings in children and adolescents continue to be common occurrences. Children younger than 6 years of age accounted for 48% of the almost 2.2 million poisoning exposure calls taken by poison centers in 2013.[1] The most common categories of products identified during poisoning calls to poison centers include cosmetics and personal care products, cleaning substances, analgesics, foreign bodies, topical agents, cough and cold preparations, vitamins, pesticides, and plants. Although many of these exposures are medically trivial, poisonings account for an important number of all pediatric hospital visits and hospitalizations. Preschool children and those with developmental delays and pica, as occurs with autistic spectrum disorders, have an increased risk for poisoning. A second peak of serious poisonings occurs in adolescence, when suicide attempts by poisoning or toxicity related to substance abuse become common circumstances.

Common Agents Involved in Serious Pediatric Poisonings

The agents most frequently involved in serious pediatric poisonings requiring intensive care include prescription medications (eg, cyclic antidepressants, anticonvulsants, cardiovascular-acting drugs, opiates), alcohols, carbon monoxide, caustic agents, and hydrocarbon-based household products. International adoptees and children immigrating to the United States may have been exposed to lead, arsenic, or other toxins in a polluted environment in their home countries or by their family's use of poorly regulated remedies. Clinicians should ask caretakers about the types and doses of any medications, herbs, vitamins, diet supplements, or ethnic remedies being given to their child. Such therapies may be interacting with the toxins responsible for the poisoning or otherwise contributing to the child's toxicity.

Resources for the Clinician

In making the diagnosis of an unknown poisoning, the physician must rely on observation, history-taking abilities, and clinical skills. Laboratory analyses and radiographic findings are sometimes helpful. The regional poison control center (US telephone: 1-800-222-1222) can provide consultative services by medically trained toxicologists.

General Assessment of the Poisoned Patient

History

An accurate history is vitally important in the diagnosis of unknown poisoning. Surprisingly, the physician in the ICU may be the first health professional who can sit with parents and carefully review the circumstances of the exposure. Poisonings may occur by various routes including ingestion, inhalation, ocular exposure, dermal exposure, mucous membrane involvement, or parenteral exposure. Once the child's condition has been stabilized, the pediatrician should query the family about the incident, with particular attention to the environmental, patient, and toxic agent factors as outlined in Table 127.1. The importance of obtaining precise ingredients or package contents cannot be overemphasized. Parents should bring the product containers and medication labels. Parents may minimize the child's exposure to a toxin in an attempt to deny the threat of injury or to assuage their guilt that such an episode occurred. Therefore it is prudent to assume a worst-case scenario in calculating the maximum dose of a drug or household product a child could have swallowed in a poisoning, using the maximum number of missing tablets or amount of liquid, the concentration of the drug or chemical, and the child's weight.

TABLE 127.1

History Taking and Unknown Poisoning in the Pediatric Patient

Environment	Patient	Toxin
Witnesses	Intentionality	Agent(s) involved
Time of ingestion	Past medical problems	Exact ingredients
Site of ingestion	Current medications	Dose (maximum estimated)
Illness of family	Known drug allergies	Concentration members
Medications of family members	Time of symptom onset	Route of exposure
Open containers	Prior medical management	

The latency between the time of ingestion and onset of symptoms is important. The tempo of progression of symptoms and signs also may help the clinician gauge the severity of the intoxication and the urgency with which intervention is necessary. However, there are some exceptions to this rule. Patients poisoned by some toxins, such as paraquat and the *Amanita* mushroom toxin, may have a relatively symptom-free period of 12 hours or more but then manifest life-threatening pulmonary or hepatic toxicity, respectively.[2,3] Some drugs, such as sulfonylurea hypoglycemics and valproic acid, can also have similar latency periods before the onset of severe toxicity.[4,5] Adolescent poisonings are confounded by the intentionality of the episode and unreliability of the adolescent's history. Adolescents in distress may be evasive, misleading, or uncommunicative. Their ability to remember or provide a coherent account of what happened may be distorted by the effects of the drugs taken. The clinician cannot assume that the time of exposure, the dose, or even the toxic agents themselves are accurately recounted.

Physical Examination

The physical examination is crucial for assessment of the patient's medical stability and for identification of the unknown poison. Specific changes in vital signs and symptoms are associated with likely toxins or groups of toxins. Such characteristic clinical patterns of illness are sometimes termed *toxidromes.* Table 127.2 lists some of the more common toxidromes. Families are using herbs and diet supplements with increasing frequency to treat their children's illnesses or simply promote their general well-being. However, serious poisonings in which herbs and dietary supplements are implicated are appearing in the medical literature.[6] Table 127.3 lists some examples of toxicities associated with particular herbal remedies.

TABLE 127.2

Common Toxidromes in Pediatric Poisoning

Signs and Symptoms	Agent
Dilated pupils, tachycardia, tachypnea, arrhythmias, hypertension, warm moist skin, flushing, sweating, agitation, nausea, vomiting, abdominal pain, delirium	Sympathomimetic syndrome
Miosis, salivation, vomiting, diarrhea, wheeze, bronchorrhea, lacrimation, seizures, weakness, tremors, coma, respiratory failure, bradycardia, urinary frequency	Organophosphate insecticides (cholinergic toxidrome)
Fever, tachypnea, hyperpnea, sweating, lethargy, metabolic acidosis (late), nausea, vomiting, tinnitus, seizures (late), coma (late)	Salicylates
Seizures, metabolic acidosis, history of tuberculosis, hyperglycemia	Isoniazid
Dry mouth and skin, flushed appearance, dilated pupils, fever, ileus, urinary retention, disorientation	Anticholinergic syndrome
Oculogyric crises, dystonia, opisthotonus	Phenothiazines
Severe metabolic acidosis, sluggish pupils, hyperemic retina, blurred vision	Methanol
Hypoglycemia, lethargy, ataxia, seizures, characteristic breath odor	Ethanol
Lethargy or coma, metabolic acidosis, active urinary sediment, crystalluria	Ethylene glycol
Headache, flulike symptoms, lethargy, dizziness, coma	Carbon monoxide
Pinpoint pupils, coma, respiratory depression, hypothermia, pulmonary edema, constipation	Opiate
Hyperthermia, akathisia, mydriasis, diarrhea, neuromuscular rigidity, autonomic dysfunction, agitation, delirium, rhabdomyolysis	Serotonin syndrome
Metabolic acidosis, prolonged QRS interval, coma, seizures, dilated pupils, dysrhythmias	Tricyclic antidepressants
Protracted vomiting, tremors, tachycardia, anxiety, seizures, hypotension	Theophylline
Feeling of impending doom, sudden coma, metabolic acidosis, hypotension, almond odor	Cyanide
Rotatory nystagmus, delirium; “4 C's”: *c*ombative, *c*atatonia, *c*onvulsions, *c*oma	Phencyclidine

TABLE 127.3

Herbs Associated With Toxicity

Herbal Product	Toxic Chemicals	Toxic Effects
Aconite (*Aconitum* spp.)	Aconitine alkaloids	Nausea, vomiting, paresthesia, weakness, hypotension, asystole, arrhythmia, bradycardia
Chamomile *(Matricaria chamomilla, Anthemis nobilis)*	Allergens	Anaphylaxis, contact dermatitis
Chapparal *(Larrea divaricata, Larrea tridentata)*	Nordihydroguaiaretic acid	Nausea, vomiting, lethargy, hepatitis
Cinnamon oil *(Cinnamomum)*	Cinnamaldehyde	Dermatitis, abuse syndrome
Coltsfoot *(Tussilago farfara)*	Pyrrolizidines	HVOD
Comfrey *(Symphytum officinale)*	Pyrrolizidines	HVOD
Crotalaria spp.	Pyrrolizidines	HVOD
Echinacea (*Echinacea angustifolia, Compositae* spp.)	Polysaccharides	Asthma, atopy, angioedema, anaphylaxis, urticaria
Eucalyptus *(Eucalyptus globulus)*	1,8-cineole	Drowsiness, ataxia, nausea, vomiting, seizures, coma, respiratory failure
Garlic *(Allium sativum)*	Allicin	Dermatitis, chemical burn, oxidant
Germander *(Teucrium chamaedrys)*		Hepatotoxicity
Ginseng *(Panax ginseng)*	Ginsenoside	Ginseng abuse, diarrhea, anxiety, insomnia, hypertension
Glycerated asafetida	Oxidants	Methemoglobinemia
Grousel *(Senecio longilobus)*	Pyrrolizidines	HVOD
Heliotrope, turnsole *(Crotalaria fulva, Heliotropium, Cynoglossum officinale)*	Pyrrolizidines	HVOD
Jin bu huan (*Stephania* spp., *Corydalis* spp.)	L-Tetrahydropalmatine	Hepatitis, lethargy, coma
Kava-kava *(Piper methysticum)*	Kavain, methysticin	Hepatic failure, "kavaism" neurotoxicity
Kelp	Iodine	Thyroid dysfunction
Laetrile	Cyanide	Coma, seizures, death
Licorice *(Glycyrrhiza glabra)*	Glycyrrhetic acid	Hypertension, arrhythmia, hypokalemia
Ma huang *(Ephedra sinica)*	Ephedrine	Arrhythmia, seizure, stroke, hypertension
Monkshood *(Aconitum napellus, A. columbianum)*	Aconite	Arrhythmia, weakness, coma, shock, paresthesia, vomiting, seizure
Nutmeg *(Myristica fragrans)*	Myristicin, eugenol	Hallucination, emesis, headache
Nux vomica	Strychnine	Seizure, abdominal pain, respiratory arrest
Pennyroyal (*Mentha pulegium* or *Hedeoma* spp.)	Pulegone	Centrilobular liver necrosis, fetotoxicity, seizure, shock
Ragwort (golden) *(Senecio aureus, Echium)*	Pyrrolizidines	HVOD
Wormwood (*Artemisia* spp.)	Thujone	Seizure, dementia, tremor, headache

HVOD, hepatic veno-occlusive disease.

Modified from Committee on Injuries & Poison Prevention. Children's Environmental Health. 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009.

Frequently, the gastrointestinal tract is involved early in a poisoning, with findings such as nausea, vomiting, abdominal pain, and diarrhea. Overdoses with cocaine, phenothiazines, atropine, or salicylates are often associated with an elevated temperature. Table 127.4 lists examples of drugs and toxic agents associated with specific effects on the cardiovascular system. Drugs with cardiotoxic effects are among those most commonly associated with life-threatening toxicity. In one 10-year retrospective study, 15 out of 17 poisoned patients requiring extracorporeal life support measures for refractory shock or prolonged cardiac arrest had overdosed on cardiotoxic agents.[7] Toxins may cause hypertension or hypotension by direct effects on vascular smooth muscle, neurogenic effects on autonomic nervous centers governing vascular innervation, direct effects on the heart, or renal effects. Specific agents associated with hypertension include adrenergic stimulants, such as amphetamines, cocaine, phencyclidine, phenylpropanolamine, ephedrine, and phenylephrine. Although the hypertension caused by sympathomimetics frequently

lasts only a few hours, it may be associated with acute encephalopathy and/or intracranial hemorrhage.

TABLE 127.4

Toxins Associated With Cardiovascular Findings

Sign	Agents
Tachycardia	Amphetamines Antihistamines Anticholinergics, atropine, *belladonna* Aconite Caffeine Cocaine Cardiac glycosides β-Adrenergic agonists (albuterol, terbutaline) Nicotine Sympathomimetic agents Theophylline
Bradycardia	Aconite Antiarrhythmics β-Adrenergic blockers Calcium channel blockers Cardiac glycosides Clonidine Ergotamine Opiates Organophosphate pesticides Phenylpropanolamine Quinidine Sedative-hypnotics
Torsades des pointes	Amantadine Antiarrhythmics Amiodarone Arsenic Astemizole Chloral hydrate Chloroquine Cisapride Cyclic antidepressants Disopyramide Encainide Fluoride Lidocaine Mexiletine Organophosphates Terfenadine Quinidine Procainamide Pentamidine Phenothiazines Prenylamine Suxamethonium
Ventricular tachycardia	Aconite Amphetamines Antiarrhythmics (eg, quinidine, flecainide) Carbamazepine Chloral hydrate Chlorinated hydrocarbons Cocaine Cyclic antidepressants Digitalis Theophylline Thioridazine

Acute hypotension is frequently associated with poisoning by aconite, antiarrhythmic agents, antihypertensive agents, β-adrenergic antagonists, calcium channel antagonists, clonidine, tricyclic antidepressants (severe), iron (severe),

opiates, and phenothiazines.

Tachycardia is frequently associated with ingestion of any of the sympathetic nervous system stimulants listed in Table 127.5. Tachycardia is also associated with ingestion of exogenous thyroid preparations, the early phase of poisoning with tricyclic antidepressants, theophylline overdoses, and caffeine or nicotine intoxications. Bradycardia may accompany exaggerated vagal responses to some compounds or direct negative chronotropic effects on the heart. Interference with the cardiac conduction system may cause a slowed pulse. Cardiac drugs associated with bradyarrhythmias include the calcium channel antagonists, digitalis, and β-adrenergic antagonists. Antiarrhythmic agents such as quinidine and procainamide can slow the pulse. Aconite, an herbal remedy, binds to site 2 of the open state of voltage-sensitive sodium channels, which then become refractory to excitation and cause arrhythmias.[8] Many drugs and chemicals depress a patient's consciousness either directly or by hypoxia resulting from decreased respiratory drive or simple asphyxia. Table 127.6 provides a suitable scoring system for determining the level of consciousness in the intoxicated patient. The dynamic nature of a poisoning mandates serial assessments of consciousness using this objective scoring system to gauge accurately whether the patient's overall condition is deteriorating or improving. In many serious intoxications, such as carbon monoxide or cyanide poisoning, the state of consciousness may be the single best guide to the patient's overall prognosis. Box 127.1 lists some of the agents that may cause coma in the pediatric patient. Box 127.2 lists some common causes of seizures.

TABLE 127.5

Reed Scale for Clinical Assessment of Consciousness

Grade	Description
0	Asleep, can be aroused, answers questions
1	Comatose, withdraws from painful stimuli, intact reflexes
2	Comatose, does not withdraw from painful stimuli, no respiratory or circulatory depression, intact reflexes
3	Comatose, reflexes absent, no respiratory or circulatory depression
4	Comatose, reflexes absent, respiratory or circulatory problems

From Ellenhorn MJ, Barceloux DG. Medical Toxicology. New York, NY: Elsevier; 1988.

TABLE 127.6

Toxins Associated With Characteristic Breath Odors

Toxin	Characteristic Odor
Acetone	Ketones
Arsenic	Garlic
Camphor	Mothballs
Chloroform	Sweet
Cyanide	Bitter almond
Ethanol	Fruity, alcohol
Hydrogen sulfide	Rotten eggs
Isopropanol	Ketones
Methyl salicylate	Wintergreen
Nicotine	Stale tobacco
Organophosphates	Garlic
N-3-pyridylmethyl-*N′*-*p*-nitrophenyl urea	Peanuts (rat poison)
Paraldehyde, chloral hydrate	Pears (urine)
Phenol, cresol	Phenolic
Phosphorus, organophosphate pesticides	Garlic
Salicylates	Acetone

Selenium	Garlic
Thallium	Garlic
Turpentine	Violets

Box 127.1

Agents Associated With Coma in the Pediatric Patient

Alcohols and glycols: ethanol, ethylene glycol, methanol
Anticonvulsants
Aromatic hydrocarbons
Asphyxiant gases
Barbiturates
Benzodiazepines
Carbon monoxide
Clonidine
Conium maculatum (water hemlock)
Cyanide
Cyclic antidepressants
γ-Butyrolactone, γ-hydroxybutyrate
Hydrogen sulfide gas
Hypoglycemic agents
Insulin
Ketamine
Lead (encephalopathy)
Lithium
Nonbarbiturate sedative-hypnotics
Opiates
Organochlorine pesticides
Phenothiazines
Propranolol
Salicylates
Tetrodotoxin

Box 127.2

Agents Associated With Seizures at Presentation

Amphetamines
Bupropion
Camphor
Carbon monoxide
Cicuta maculatum (water hemlock)
Cocaine
Cyanide
Ephedrine
Gyromitra (mushroom species)
Insulin
Isoniazid
Methylene dioxymethamphetamine (MDMA)

Monoamine oxidase inhibitors
Nicotine
Organophosphate, organochlorine pesticides
Phencyclidine
Phenylpropanolamine
Phenothiazines
Propoxyphene
Salicylates
Scorpion
Strychnine
Tetanus
Theophylline
Tricyclic antidepressants

Pupil size depends on the balance between dilating and constricting fibers and is under complex autonomic nervous system control. Both sympathetic and parasympathetic nerves regulate the iris and can be affected by a variety of toxins. Anticholinergic drugs such as tricyclic antidepressants, antihistamines, and belladonna paralyze the parasympathetic fibers leading to pupillary dilation. Conversely, agents that inactivate cholinesterase leading to accumulations of acetylcholine (eg, organophosphate pesticides, physostigmine) constrict the pupil. Ethanol, phenothiazines, and barbiturates also constrict the pupils. Opiates act centrally to cause extreme pupillary constriction (miosis). Sympathomimetics, such as amphetamines and cocaine, cause extreme pupillary dilation (mydriasis). Pilocarpine directly stimulates the sphincter muscle of the iris, causing constriction. Toxins can also be responsible for unequal pupil size. Instillation of atropine to the eye causes ipsilateral pupillary dilation. Polydrug overdoses may include agents with opposite pupillary actions, so overreliance on pupillary size alone in deciding which poison is responsible for the patient's condition may lead to a misdiagnosis. Closed head trauma or central nervous system (CNS) hemorrhage, sometimes seen in the context of a poisoning with hypertension-inducing drugs such as phenylpropanolamine or ephedrine[9] can themselves cause pupillary effects.

When treating a disoriented, delirious pediatric patient, the clinician must consider which intoxications may be responsible. Because of their central anticholinergic effects and common availability, antihistamines (eg, chlorpheniramine, diphenhydramine) must be considered. Alcohol-containing household products or liquor may be responsible. In the adolescent, substances of abuse may cause delirium or hallucinations. Jimsonweed *(Datura stramonium)* plant seeds, containing atropine and other anticholinergic chemicals, can be intentionally chewed by adolescents for their euphoric (and delirium-producing) effects caused by a central anticholinergic syndrome. Hallucinogens include lysergic acid diethylamide (LSD), psilocybin, mescaline, “magic mushrooms,” and some amphetamine congeners (“designer drugs,” eg, 3-methoxy 4,5-methylenedioxyamphetamine [MMDA], 3,4-methylenedioxy-*N*-methamphetamine [MDMA, “ecstasy”], or 3,4-methylenedioxy-*N*-ethylamphetamine [MDEA]). Both cocaine and amphetamines can cause an acute psychosis. Smokable forms of methamphetamine (known as “crystal” or “ice”) and phencyclidine (PCP) cause symptoms of agitation, aggression, and combativeness. Additionally, intensivists

should be alert for abstinence syndromes in adolescents suffering from chronic substance abuse. Drug withdrawal from opiates, benzodiazepines, or alcohol (delirium tremens) often causes agitation, irritability, or even delusional thinking in affected patients. Withdrawal from chronic γ-hydroxybutyrate use (GHB, a popular "designer drug") is characterized by anxiety, insomnia, tremor, confusion, delirium, hallucinations, cardiovascular changes, nausea, vomiting, and diaphoresis.[10] Other neurologic findings may be found depending on the drug or toxin. Phenytoin and phencyclidine frequently cause nystagmus. Opsoclonus (saccadic eye movements) can be caused by lithium. Tinnitus is associated with ingestions of ergot, quinine, salicylates, or streptomycin. Changes in color vision may be seen in chronic digitalis overdose or cinchonism (quinidine).

Many poisonings cause cutaneous manifestations. Abusers of IV narcotics or other drugs may have needle tracks, characteristic tattoos, or scarring from "skin popping." Those suffering from inhalant abuse frequently have rashes around the nose and mouth as a result of defatting and irritative effects of inhaled solvents. Methemoglobinemia can cause an acute cyanotic appearance despite relatively normal blood gas values. A variety of rashes can be seen with adverse drug reactions and allergic responses to drugs, plants, or chemicals. Typical chemical burns may result from dermal exposure to caustics. Alopecia is associated with exposures to antimetabolite medications, other antineoplastic agents, or overdoses of chemicals such as arsenic, thallium, and selenium. Jaundice may result from exposure to hepatotoxins such as carbon tetrachloride, aniline dyes, quinacrine, or phenothiazines.

The physician must be alert to characteristic odors in containers found at the scene of the exposure, of substances spilled on the patient's skin or clothing, or on the patient's breath. Organophosphate insecticides and thallium impart the strong odor of garlic. Cyanide exposures have the characteristic aroma of bitter almond (although 50% of the population is of the genotype that cannot detect the odor). Ethanol, kerosene, camphor, and gasoline impart their strong odors to the breath. Adolescents abusing glues or volatile organic compounds by inhalation may have a solvent smell on their breath and clothes. Table 127.7 lists some of the typical intoxications that can be diagnosed by the patient's breath odors.

TABLE 127.7

Osmolar Gap Conversions to Calculate Blood Concentration

Toxin	Conversion Factor
Methanol	2.6
Ethanol	4.0
Ethylene glycol	5.0
Acetone	5.5
Isopropanol	5.9

Serum concentration (mg/dL) of given toxin divided by corresponding conversion factor equals serum osmolality (mOsm/kg H_2O) attributable to that toxin.

Laboratory Tests and Toxin Screens

Although laboratory testing of the blood or urine occasionally reveals an unanticipated toxin involved in an overdose, more frequently it confirms the

physician's clinical diagnosis on the basis of a careful history and physical examination. The pediatric intensivist is well advised to know which compounds are included in the toxicology screen performed by the institution because the menu of substances detectable by a commercial laboratory is variable and frequently based on cost, ease of detection, available technical equipment, relative frequency of the overdose in the community, and other considerations. Most hospitals include the following compounds on a toxicology screen: acetaminophen, ethanol, barbiturates, opiates, anticonvulsants, some benzodiazepines, phenothiazines, and salicylates. Toxicology screens may or may not include certain drugs of abuse (eg, amphetamines, cocaine, tetrahydrocannabinol); older tricyclic antidepressants (eg, amitriptyline, imipramine); and methanol. Many common toxic agents, including carbon monoxide, cyanide, methemoglobin, iron, lithium, heavy metals such as lead or arsenic, and ethylene glycol, are never included in a toxicology screen and must be ordered specifically. For these reasons, a "negative" toxicology screen does not rule out the diagnosis of a poisoning. The more specific a clinician is in communicating with laboratory personnel about which toxins are suspected clinically, the more directed laboratory personnel can be in seeking specific answers through laboratory methods. Because some toxins (eg, cocaine, other drugs of abuse, some heavy metals) are detected more easily in urine than in the blood, both specimens should be submitted when the toxicology screen is ordered. Reliability in the screening for drugs or toxins requires not only a sound analytic technique but also adequate sample collection, chain of custody, and timely reporting of the results. Sources of error include delay in the time between sample collection and assay; problems with sample collection (wrong patient, wrong tube, loss of fluid, poor labeling); natural chemical reactions (volatilization, enzymatic degradation); purposeful sample alteration; technical limits on the detection threshold of the assay used; and misinterpretation of the units in reporting the results. Blood concentrations of acetaminophen, aspirin, barbiturates, carbamazepine, carbon monoxide, digoxin, ethanol, ethylene glycol, iron, isopropanol, lead, lithium, methanol, phenobarbital, phenytoin, theophylline, and valproic acid are useful in assessing the severity of the intoxication and guiding patient management. Co-oximetry can provide blood levels of abnormal hemoglobins caused by toxins, such as carboxyhemoglobin, sulfhemoglobin, and methemoglobinemia. Note that pulse oximetry gives inaccurate readings in patients with methemoglobinemia because methemoglobin absorbs more light at both 660 and 940 nm than does oxyhemoglobin, so the readings of oxygen saturation may seem normal in the presence of severe methemoglobinemia. Indeed, the blood drawn from a patient with significant methemoglobinemia will appear "chocolate" brown in color. Box 127.3 lists drugs, chemicals, and foods capable of causing methemoglobinemia in susceptible individuals.

Box 127.3

Drugs, Chemicals, and Foods Causing Methemoglobinemia

Drugs

Acetanilid

Amyl nitrite
Benzocaine
Cetacaine
Chloroquine
Chloroquine
Clofazimine
Dapsone (sulfones)
Diaminodiphenylsulfone
Hydroxylamine
Lidocaine
Menadione
Methylene blue
Metoclopramide
Nitroglycerin
Nitrosobenzene
Para-aminobenzoic acid
Para-aminopropiophenone
Para-hydroxylaminopropiophenone
Phenacetin
Phenazopyridine hydrochloride (Pyridium)
Phenylhydroxylamine
Phenytoin
Potassium permanganate
Prilocaine
Primaquine
Procaine
Resorcinol
Silver nitrate
Sodium nitrate
Sodium nitrite
Sodium nitroprusside
Sulfamethoxazole
Sulfanilamide
Sulfapyridine
Sulfathiazide

Chemicals

Acetanilid
Alloxan
Ammonium nitrate
Aniline dyes
Antipyrine
Arsine
Benzene derivatives
Butyl nitrite
Chlorates
Chlorobenzene
Cobalt preparations

Dimethylaniline
Dinitrobenzene
Dinitrophenol
Dinitrotoluene
Hydroquinone
Inks/shoe polish
Isobutyl nitrite
Menthol
Naphthalene
Naphthylamines
Nitrates/nitrites
Nitric oxide
Nitroalkanes
Nitrobenzene
Nitrofuran
Nitrogen oxide
Nitrogen trifluoride
Nitroglycerin
Nitrophenol
Nitrous gases/nitric oxide
Ozone
Para-bromoaniline
Paraquat (or Monolinuron)
Para-toluidine
Phenazopyridine
Phenetidin
Phenols
Phenylhydrazine
Phenylhydroxylamine
Pyridine
Smoke (products of combustion)
Sulfones
Toluidine
Trinitrotoluene
Xylidine

Foods

Beets, cabbage, spinach
Nitrite/nitrate preservatives, Nitrogen-rich foods, Well water (elevated nitrates)

Certain toxins (eg, ethanol, ethylene glycol, isopropanol, methanol) introduce osmotically active particles into the serum. These particles increase serum osmolality, which can be measured by either vapor pressure or freezing point depression. However, vapor pressure techniques give falsely low values in the presence of volatiles (such as any of the alcohols) and should not be used in the monitoring of poisoning cases. The calculated serum osmolality is derived by the following equation: Calculated serum osmolality = [2 × Na (in mEq/L)] + [Blood urea nitrogen (in mg/dL)/2.8] + [Glucose (in mg/dL)/18].[11] Calculated osmolality can then

be subtracted from the measured osmolality to assess the osmolar gap. A normal osmolar gap is between −3 and 10 mOsm/kg H_2O. Blood alcohol concentration can be estimated using the serum osmolality as measured by the freezing point depression technique, then calculating the osmolar gap, and applying the conversion factors listed in Table 127.8. Intensivists are cautioned that elevated osmolar gaps are also seen in patients with lipemic blood or in those receiving therapies such as mannitol, intralipid, glycerol, sorbitol, propylene glycol, or some radiocontrast agents. Conversely, a falsely low osmolar gap can be seen in ethylene glycol or methanol poisoning if the vapor pressure method of serum osmolality determination is erroneously used instead of freezing point depression.

TABLE 127.8

Useful Diagnostic Trials

Agent Detected	Agent Administered	Technique	Positive Results
Anticholinergic agents (pure)	Physostigmine	0.01-0.02 mg/kg over 15 seconds (rate no greater than 0.5 mg/minute); may repeat at 5-10 minute intervals thereafter × 4 (max 0.05 mg/kg or 2 mg total)	Improved conscious
Benzodiazepines	Flumazenil	0.01-0.02 mg/kg (maximum dose 0.2 mg) IV over 15 seconds, may repeat every minute thereafter × 4 up to maximum cumulative dose 0.05 mg/kg or 1 mg [whichever is less]	Improved conscious
Iron	Deferoxamine	15 mg/kg/hr IV drip (max 125 mg/hr)	"Vin rose" urine color
Opiates	Naloxone hydrochloride	0.1 mg/kg IV/IM/SC/IO for birth to 5 years of age (<20 kg body weight) or 2 mg per dose IV/IM/SC/IO for weight >20 kg	Improved conscious
Organophosphate	Atropine	0.05-0.10 mg/kg IV/IM/IO (4 mg maximum dose); repeat every 5-10 minutes for moderate-severe OP poisoning	Mydriasis, fewer secretions
Phenothiazine (dystonia)	Diphenhydramine	1-2 mg/kg slow IV over 5 minutes (maximum rate: 25 mg/minute); may repeat × 4 doses per day (maximum cumulative dose: 300 mg/day)	Resolution
Phenothiazine (NMS)	Dantrolene	1 mg/kg IV (maximum cumulative dose 10 mg/kg)	Resolution
Insulin reaction	Dextrose	10% dextrose in water; 2.5 mL/kg IV bolus	Improved conscious
Isoniazid	Pyridoxine	5 grams (if isoniazid overdose quantity unknown), or gram per gram of isoniazid overdose	Seizures abate; improved conscious
Sulfonylurea	Octreotide	1-1.5 mcg/kg IV or SC followed by 2-3 doses every 6 hours as needed	Resolution of hypoglycemia

NMS, neuroleptic malignant syndrome.

The principle of electroneutrality requires that positive and negative charged molecules in the serum must balance. Toxins that cause metabolic acidosis frequently increase the gap between the total measured versus theoretical anions by the direct addition of organic acid anions, the indirect generation of such anions, or (rarely) the reduction of cations in the serum. The anion gap calculation is derived as follows: Anion gap = $Na^+ - (Cl^- + HCO_3^-)$, where all components are expressed in milliequivalents per liter. The "normal" anionic gap ranges from 3 to 16 mEq/L in older children and adults. Hypoalbuminemia or diluted blood both cause misleadingly low anion gaps, as can poisoning with cations such as lithium or bromide. The presence of elevated concentrations of unmeasured anions (eg, as a result of dehydration or treatment with sodium salts of citrate, lactate, or acetate) or conditions associated with a decrease in unmeasured cations (eg, as a result of hypomagnesemia, hypocalcemia, hypokalemia) can lead to an elevated anion gap.

Poisoning with drugs such as isoniazid, iron, paraldehyde, phenformin, or salicylate or chemicals such as ethylene glycol or methanol can lead to a metabolic acidosis with an elevated anion gap.

Many agents that cause seizures (eg, isoniazid, organochlorine pesticides, theophylline, tricyclic antidepressants) or agitation, excessive muscular activity, and hyperthermia (eg, cocaine, amphetamines, phencyclidine, neuroleptic malignant syndrome, serotonin syndrome) may predispose the patient to rhabdomyolysis and subsequent myoglobin-induced acute renal failure. The overdose patient who is agitated or delirious and is held in physical restraints for long periods of time and the overdose comatose patient who has muscle necrosis from dependency position injury are at high risk for rhabdomyolysis. In such circumstances, monitoring serum lactic acid, creatine phosphokinase, aldolase, myoglobin, urinary sediment, urine output, and urinary myoglobin levels may be useful.

Additional Investigations

Radiographic Studies

Radiographs can be helpful in locating swallowed foreign bodies having toxic potential. Patients who have ingested disk batteries should undergo serial chest and abdominal radiography to ensure that the battery has cleared the esophagus and is continuing to move along the gastrointestinal tract. Drug smugglers who have swallowed quantities of heroin or cocaine-filled balloons, condoms, or other containers can be diagnosed as a "body packer" by radiographic examination.[12] Chest and abdominal x-ray films may be of value in locating pills, tablets, or lead-containing paint chips. Sometimes agglutinated masses of pills (bezoars) can be detected in this manner. Box 127.4 lists some drugs and chemicals that may be visualized in imaging studies.

Box 127.4

Drugs and Chemicals That May Be Radiopaque

Bezoars, bags (filled with illegal drugs)
- Calcium carbonate
- Chloral hydrate
- Enteric-coated tablets
- Foreign bodies (sometimes radiopaque)
- Heavy metals (eg, iron, lead, mercury, thallium)
- Iodine
- Lithium carbonate
- Paradichlorobenzene mothballs
- Phenothiazines
- Potassium compounds

Diagnostic Trials

For a few suspected toxins, administration of an antidote not only initiates therapy but also assists in the diagnosis of the agent involved. Table 127.8 lists some of the diagnostic trials that may be appropriate in the pediatric ICU setting. For example,

flumazenil, a specific benzodiazepine antagonist, can be used as a diagnostic agent administered to the comatose patient. At an IV dose of 1 to 2 mg, adults show a rapid improvement in consciousness (analogous to naloxone's effectiveness in reversing narcotic-induced CNS depression) after overdose involving a variety of benzodiazepines. Caution must be exercised; if a second, seizure-causing agent such as a tricyclic antidepressant has also been coingested, then the reversal of the benzodiazepine's anticonvulsant effects may inadvertently unmask seizures in the victim. Physostigmine can be of benefit in pediatric patients who have ingested Jimsonweed seeds *(D. stramonium)* or other pure anticholinergic agents; however, caution is dictated in unknown poisonings where cardiac conduction toxicity is a consideration because physostigmine itself can cause severe cardiac toxicity, bradycardia, and asystole.[13]

Summary

Intensive care physicians face some of their greatest diagnostic challenges when confronted with patients who are admitted to the hospital with a baffling constellation of symptoms and signs and whose differential diagnosis includes poisoning. The history alone will often clarify the clinical picture, suggesting potential drugs or toxins that might be responsible for the patient's illness. Physical findings attendant to a comprehensive examination of the patient, with a focus on vital signs and the skin, gastrointestinal, cardiovascular, pulmonary, and neurologic systems, may confirm the clinician's suspicions. Knowledge of common toxidromes can help the intensive care physician recognize which poison or pharmacologic category of toxic agents may be responsible. The nearest regional poison center has 24-hour availability of medical toxicology expertise. For a few suspected toxins, diagnostic studies can be helpful in the assessment of the severity of toxicity and in the prediction of a patient's expected hospital course. Quantitative blood or urine levels of some drugs or chemicals can be invaluable in both the patient's assessment and monitoring. The investigation of anion or osmolar gaps, derangements in blood gases or electrolytes, electrocardiographic abnormalities, and imaging studies will often be indicated in critically ill patients. Administration of an antidote in selected cases may not only initiate therapy but also assist in the diagnosis because improvement in a patient's status soon after receipt of the antidote may confirm the poison involved. Close monitoring of the patient over time is essential to optimal management of the poisoning.

CHAPTER 128

Toxidromes and Their Treatment

Ashley N. Webb, Prashant Joshi

PEARLS

- Flumazenil, when used for benzodiazepine overdose, may unmask seizures caused by a coingested substance or precipitate acute withdrawal in the patient who habitually uses benzodiazepines.
- β-Adrenergic antagonists, when used to lower blood pressure in a sympathomimetic overdose, may lead to unopposed α-receptor stimulation and should be avoided.
- Reserve physostigmine administration for severe, life-threatening manifestations of anticholinergic toxicity because it may lead to asystole or seizures. It is contraindicated for reversal of anticholinergic symptoms produced by tricyclic antidepressant ingestion.
- Pulse oximetry is unreliable for determining oxygen saturation with methemoglobinemia and may show falsely elevated or decreased values.
- Use the skin to distinguish between sympathomimetic (pale, cool, and diaphoretic) and anticholinergic (flushed, warm, and dry) toxidromes.
- Malignant hyperthermia, serotonin syndrome, neuroleptic malignant syndrome, sympathomimetic poisoning, and anticholinergic poisoning constitute the major differential diagnosis for xenobiotic-induced hyperthermia.
- An elevated osmolar gap may suggest ingestion of a toxic alcohol, but a normal result does not exclude it. Serum toxic alcohol levels are the gold standard for diagnosis and prognosis.
- Succinylcholine is relatively contraindicated in cholinesterase inhibitor toxicity because its duration of effect will be significantly prolonged.
- Total iron-binding capacity may be falsely elevated in patients with acute iron overdose and is not a reliable marker in iron toxicity.
- In the United States, the local Regional Poison Control Center may be reached by calling 800-222-1222.

The 31st annual report of the American Association of Poison Control Centers

described more than 2 million human exposures to toxic substances that were reported to poison control centers in the United States in 2013.[1] Approximately 55% involved children younger than 12 years, but this age group accounted for only about 3% of the reported fatalities. Although 70% of these exposures were managed without further medical assistance, of the 30% of patients who were referred and seen in a health care facility, one in six was admitted to a critical care unit. Calls from health care facilities to poison control centers are increasing and account for a growing proportion of cases handled by poison control center specialists.

In most cases of childhood poisoning, the agents involved are known or circumstantial evidence points to a specific toxin or toxins. When the toxin is unknown or the clinical presentation is inconsistent with the available exposure history, physical and analytic clues will help guide therapy. *Toxidrome* is a contraction of *toxic syndrome,* a constellation of signs associated with certain substances or groups of substances. Recognition of a toxidrome provides for targeted investigation and treatment. Toxidrome expression may not be complete in every case, or more than one toxidrome may be present. During the initial patient examination, clinicians pay particular attention to vital signs, mental status, pupil size and reactivity, skin characteristics (color, temperature, moisture), and bowel sounds. Other important aspects to consider include muscle tone, respiratory effort, and mucous membrane characteristics.

As discussed in Chapters 127, laboratory investigations may narrow the differential diagnosis and determine the need for additional examination or guide therapy. However, clinicians must review these diagnostic tests with caution. Many assays lack sensitivity and specificity to confirm specific substances, so an inaccurate diagnosis or inappropriate therapy, including withholding a specific antidote, is a consequence of relying on these assays alone.[2] In conjunction with clinical findings and exposure history, assays are chosen based on their probability of indicating or guiding therapy and prognosticating end-organ toxicity.

This chapter describes commonly accepted toxidromes as well as less common yet relevant toxic presentations and their treatments. More in-depth information can be found in a comprehensive textbook of medical toxicology.

Opioids

Both natural and synthetic opioids produce the classic triad of respiratory depression, coma, and miosis. Additional features include bradycardia, hypotension, and decreased gastrointestinal (GI) motility.[3] Not all patients exposed to an opioid present with the classic toxidrome; for example mydriatic or midpoint pupils are seen with specific opioids, although brain anoxia or coingestants should also be considered (Box 128.1).[3-5]

Box 128.1

Opioids That Cause Midpoint or Mydriatic Pupils

Meperidine

Pentazocine

Diphenoxylate/Atropine

Propoxyphene

Simple hypercarbia may be detected before severe overt respiratory depression.[6-9] Because decreased respiratory drive is a result of μ-receptor agonism but analgesic effect results from action at both μ- and κ-receptors, some opioids are designed to function as agonist-antagonists to provide spinal analgesia and simultaneously antagonize μ-receptors.[6,7] Other opioids, like buprenorphine, are designed to function as only partial agonists at μ-receptors, providing pain relief at higher doses with a ceiling effect on respiratory depression.[10] In overdose, lost receptor selectivity may still result in decreased respiratory drive with this type opioid medication. In overdose and in opioid-naïve pediatric patients, buprenorphine often causes overt respiratory depression, so close monitoring of respiratory status is warranted.[10-12]

Several potent opioids are extremely toxic in small doses in both the opioid-naïve and pediatric populations. Methadone liquids are concentrated, and even as little as one tablet has led to fatality.[13,14] Fentanyl, in dosage forms that allow for buccal absorption, may be attractive to children. Used fentanyl patches still contain high doses of drug and are extremely dangerous when placed on skin, in the mouth, or ingested.

Central α-2 adrenergic agonists including clonidine, guanfacine, tizanidine, and other imidazoline derivatives (found in over-the-counter eye drops or nasal sprays) can precipitate an opioid-like toxidrome.[15-18] In addition to bradycardia and hypotension, exposure to these agents in small doses may lead to CNS and respiratory depression and miosis.

Naloxone is a μ-receptor antagonist that reverses the toxic effects of opioids. To prevent the need for artificial ventilation in life-threatening opioid-induced respiratory depression, start with a dose of 0.1 mg/kg. If no intravenous access is available, administration can proceed subcutaneously, intramuscularly, or via endotracheal tube (although the intramuscular route exhibits variable pharmacokinetics with a less predictable duration of action).[19] Naloxone may precipitate acute withdrawal in opioid-dependent individuals warranting a lower starting dose, titrated upward to effect and not exceeding 10 mg cumulatively.[20] Because the duration of action of naloxone is shorter than that of some opioids, repeated doses or a continuous intravenous infusion may be necessary; the suggested infusion rate is two-thirds the initial reversal dose per hour, titrated to effect, with half the initial reversal dose given as a bolus. Respiratory and mental status are monitored for 24 hours following cessation of a prolonged naloxone infusion.[21] Although naloxone has precipitated transient hypertension or pulmonary edema in rare cases, these risks do not preclude its use.[22-24] Reports that naloxone has reversed clonidine overdose are anecdotal, and naloxone failure has also been described in this setting, so the benefit of naloxone in the face of central α-2 adrenergic agonists is unclear.[25]

Sedative Hypnotics

The class *sedative hypnotics* comprises medications that reduce CNS excitation, prescribed for their hypnotic and anxiolytic effects. Usually, sedative hypnotics

enhance γ-amino butyric acid (GABA) activity and its effect on chloride channels in the brain and spinal cord. Barbiturates act as agonists at $GABA_A$ receptors prolonging the flow of chloride through the channel resulting in hyperpolarization. Benzodiazepines, on the other hand, work at the benzodiazepine location on the $GABA_A$ receptor to enhance GABA binding and increase the frequency of chloride channel opening—they will not work in the absence of GABA.[26,27] Newer nonbenzodiazepine sedative hypnotics (zolpidem, zopiclone, and eszopiclone) also bind to the benzodiazepine location on $GABA_A$, but because of their affinity for different isoforms of the receptor, they act quickly to induce hypnosis with little effect on anxiolysis.[28] Initial reports indicated that these so-called z-drugs were a safe alternative to benzodiazepines, but more recent data depict a similar toxicity profile.

Barbiturate overdose, characterized by CNS and respiratory depression, may be associated with hypotonia, hypotension, and hypothermia, as well as bullous skin lesions.[26] On the other hand, benzodiazepine and z-drug toxicity are often referred to as "coma with normal vitals," where patients exhibit CNS depression without overt respiratory depression or autonomic dysfunction.[26,28] In one published report, ataxia was the most common symptom, so benzodiazepine ingestion should be considered in the differential diagnosis of ataxia with no additional findings.[29] Unlike opioid toxicity, low benzodiazepine receptor density in the brain stem means benzodiazepines and z-drugs pose a low risk for centrally mediated apnea.[27] Although apnea has been reported with intravenous benzodiazepine administration, therapeutic and supratherapeutic oral doses cause airway resistance and increased work of breathing.[30] In benzodiazepine overdose, patients are often described with sonorous respirations and apnea is rare.

Significant respiratory depression with benzodiazepines usually only occurs from mixed-drug ingestions or in the presence of ethanol. Most pediatric exposures are unintentional single substance ingestions posing less risk. Reversal of benzodiazepines with the benzodiazepine receptor antagonist flumazenil is usually not warranted and is in fact contraindicated in a polysubstance overdose, especially when cyclic antidepressants are suspected.[31] Removing the antiepileptic effect of a benzodiazepine may unmask seizure activity and increase morbidity. Caution is also warranted in patients with an underlying seizure disorder in whom flumazenil may lower the seizure threshold and in patients habituated to benzodiazepines where reversal may precipitate life-threatening withdrawal.[32-34] Flumazenil may reverse CNS depression, but in dose effectiveness studies, it did not significantly affect respiratory insufficiency.[30]

Withdrawal from benzodiazepine and nonbenzodiazepine sedative hypnotics, similar to ethanol withdrawal, results from down-regulation of inhibitory GABA receptors and increased excitatory *N*-methyl-D-aspartate (NMDA) binding sites. This imbalance is characterized by CNS stimulation, flushing, hypertension, tachycardia, hyperthermia, and seizures. Treatment is based on symptom reduction via replacement of benzodiazepines at the established dose and tapering as tolerated.[35]

Sympathomimetic Agents

Signs and symptoms of sympathetic excess result from both therapeutic and illicit agents that either mimic endogenous excitatory neurotransmitters or act on receptors

to increase their release.[36] Manifestations of the sympathomimetic toxidrome and some drugs that produce it are listed in Box 128.2. Predominantly β-adrenergic agents cause peripheral vasodilation more likely resulting in tachycardia and hypotension than predominantly α-adrenergic agents (severe hypertension with reflex bradycardia).[37] Hyperthermia, rhabdomyolysis, and myoglobinuria may result from increased metabolic activity; ischemic or hemorrhagic stroke and myocardial infarction have been documented.[38] Following cocaine exposure, patients may present with chest pain from coronary vasospasm; however, myocardial infarction (MI) must be ruled out.

Box 128.2

Sympathomimetic Toxidrome Features

Sympathomimetic Toxidrome	Causative Agents
Agitation	Albuterol
Seizures	Amphetamines
Mydriasis	Caffeine
Tachycardia	Catecholamines
Hypertension	Cocaine
Diaphoresis	Ephedrine
Pallor	Ketamine
Cool skin	Phencyclidine (PCP)
Fever	Phenylephrine
	Phenylpropanolamine
	Pseudoephedrine
	Terbutaline
	Theophylline

Methylxanthines, caffeine and theophylline, are not sympathomimetics per se but may produce many of the same clinical features from their β-adrenergic activity, adenosine antagonism, and phosphodiesterase inhibition.[37,39] Although most acute cases of caffeine toxicity would be limited by undesirable effects with increasing dose, the risk for potentially life-threatening caffeine exposures is higher than ever with accessible concentrated caffeine powders (as herbal supplements) and caffeine-laden energy drinks. Methylxanthine toxicity is characterized by protracted emesis, palpitations, chest pain, tachycardia, and tachydysrhythmias—most commonly supraventricular tachycardia.[40,41] A wide pulse pressure results from peripheral vasodilation, and hypokalemia occurs via an intracellular potassium shift. Neurologic symptoms range from headache to refractory seizures. Antiemetic therapy with 5-HT antagonists is recommended, but phenothiazines are contraindicated and may worsen toxicity. Norepinephrine and phenylephrine are vasopressors of choice. Severe hypotension might best be treated with a beta-antagonist. Because the offending agent is still present, electrocardioversion for supraventricular tachycardia (SVT) will be transient as will adenosine (adenosine antagonism). Judicious use of benzodiazepines is recommended to treat seizures, tachycardia, hypertension, and agitation. Consider a calcium channel or beta-receptor antagonist for arrhythmias.[42,43] Methylxanthines are dialyzable; in the case of theophylline, multiple-dose–activated charcoal is strongly recommended to remove the drug from the systemic system.[44,45]

Designer amphetamines, such as methylenedioxyamphetamine (MDMA) and its derivatives, release serotonin and may precipitate hallucinations as well as the

sympathomimetic effects listed earlier. Affected patients are at risk for seizures, dysrhythmias, hyperthermia, rhabdomyolysis, the syndrome of inappropriate secretion of antidiuretic hormone resulting in hyponatremia, and disseminated intravascular coagulation.[37,42,46] Since the early 2000s, designer amphetamine exposures have been increasing. This group now includes cathinone derivatives, referred to as bath salts (in an attempt to mask their status as illicit substances), that can be consumed, smoked, or injected.[47] Synthetic cannabinoids, referred to as spice, may cause symptoms similar to tetrahydrocannabinol (THC), the active ingredient in marijuana, with mild exposure.[47,48] Like THC, synthetic cannabinoids bind cannabinoid receptors, but they do so at a higher affinity, and because synthetic cannabinoids are usually sprayed on plant material, additional unknown substances may be present. Many cases of synthetic cannabinoid exposure appear sympathomimetic in nature and should be treated as cases involving an amphetamine. Reports of significant morbidity and mortality describe severe psychomotor agitation, aggressive psychotic behavior, seizures, tachycardia, hypertension, dysrhythmias, hyperthermia, and myocardial infarction and exist for both bath salts and spice.[47,48]

To reduce CNS catecholamine release and eliminate severe hypertension, tachycardia, agitation, and muscle overactivity, benzodiazepines are considered first (potentially large doses). β-adrenergic antagonists may paradoxically worsen hypertension from resulting unopposed α-adrenergic receptor stimulation and should be avoided (except in the case of methylxanthines where appropriate use may relieve symptoms). A vasodilator can be used for hypertension refractory to benzodiazepines; however, it must be short acting, as cocaine and similar agents may deplete norepinephrine leading to cardiovascular collapse.[38,42,47-49] Benzodiazepines should be used as first-line agents to manage seizures. Phenytoin does not treat toxin-induced seizures and, in the case of methylxanthines, it may worsen patient outcome by lowering the seizure threshold.[42]

Anticholinergic Agents

The anticholinergic, or antimuscarinic, toxidrome is elicited by agents that possess antimuscarinic properties as their primary effect or as a side effect. Muscarinic receptors are found in the CNS, target organs of the parasympathetic nervous system (PNS), and sweat glands (sympathetic nervous system).[49] This syndrome may have features similar to the sympathomimetic toxidrome. Some anticholinergic agents and features of the anticholinergic toxidrome are listed in Box 128.3. The anticholinergic patient will exhibit dry skin rather than increased diaphoresis as seen with sympathomimetic toxicity. Catheter placement may be necessary to address significant urinary retention, and dilated pupils are usually nonreactive as a result of associated cycloplegia (also not seen with sympathomimetic toxicity).[49,50]

Box 128.3

Anticholinergic Toxidrome Features

Anticholinergic Agents	Anticholinergic Toxidrome Features
Antihistamines (eg, diphenhydramine, hydroxyzine) Atropine	Agitation Delirium

Benztropine mesylate Carbamazepine Cyclic antidepressants Cyclobenzaprine Hyoscyamine Jimsonweed Oxybutynin Phenothiazines Scopolamine Trihexyphenidyl	Coma Mydriasis Dry mouth Warm, dry, flushed skin Tachycardia Hypertension Fever Urinary retention Decreased bowel sounds

It is critical to monitor core temperature and actively cool hyperthermic patients because sweating is inhibited in the face of anticholinergic toxicity. Consider benzodiazepines first to treat agitation and prevent heat production from excessive muscle activity. Although physostigmine is a cholinesterase inhibitor that may reverse central and peripheral manifestations of anticholinergic toxicity, case reports describing convulsions or asystole preclude its use for the anticholinergic manifestations of tricyclic antidepressant overdose—it is contraindicated in this setting.[49,51,52] Consultation with a medical toxicologist is warranted to determine the right patient and right time for physostigmine, where clinical benefit outweighs the risk of morbidity and mortality.[53]

Cholinergic Agents

Cholinergic agents are best divided into the following three categories: muscarinic agents, nicotinic agents, and cholinesterase inhibitors. Muscarinic agents act in the CNS, at postganglionic parasympathetic nerve endings, and in the sweat glands. Nicotinic agents act in the CNS, in the autonomic ganglia (both sympathetic and parasympathetic), and at the neuromuscular junction. Cholinesterase inhibitors increase acetylcholine in the cholinergic synapse to present a combination of symptoms resulting from action at both nicotinic and muscarinic receptors.[54,55] Agents with cholinergic activity and signs and symptoms of cholinergic excess are listed in Boxes 128.4 and 128.5.

Box 128.4

Xenobiotics Causing Cholinergic Excess

Inhibitors of Acetylcholinesterase	Direct Muscarinic Agonists	Nicotinic Agents
Organophosphate insecticides (malathion, parathion, diazinon) Carbamate insecticides (aldicarb, carbaryl, propoxur) Nerve agents (soman, sarin, tabun, Vx, cyclosarin) Drugs used for myasthenia gravis or reversal of neuromuscular blockade (eg, physostigmine, pyridostigmine, neostigmine, edrophonium)	Bethanechol Carbachol Methacholine Pilocarpine Muscarinic mushrooms (eg, *Clitocybe* spp., *Inocybe* spp.)	Nicotine Water hemlock

Box 128.5

Cholinergic Toxidrome Features

Muscarinic Effects (DUMBBBELS)	Nicotinic Effects	Central Effects
D—Diarrhea U—Urinary incontinence	Fasciculations Weakness	Lethargy Coma

M—Miosis B—Bradycardia B—Bronchorrhea B—Bronchospasm E—Emesis L—Lacrimation S—Salivation	Paralysis Tachycardia Hypertension Agitation	Agitation Seizures

Nicotine produces salivation, nausea, and vomiting, but significant exposure results in hypotension, bradycardia, and respiratory depression, often preceded by tachycardia, hypertension, and tachypnea.[54-58] Central features include initial stimulation followed by seizures, lethargy, coma, and neuromuscular blockade. Management of nicotine poisoning is entirely supportive with consideration of atropine for bradycardia, close monitoring, and aggressive respiratory support.[56-59] Children are at increased risk of nicotine poisoning from ingestion of cigarettes or chewing tobacco, exposure to smoking cessation products (gums, lozenges, patches, and inhalers), and, more recently, exposure to concentrated liquid nicotine associated with electronic cigarettes.[60-62] Because liquid nicotine intended for vaporization and inhalation is in a highly concentrated form when used with e-cigarette cartridges or in vials for refillable e-cigarettes (10 mg/ml to greater than 24 mg/ml), very small exposures may cause toxicity, usually seen at doses greater than 30 mg. These concentrates are easily absorbed through the skin and GI tract, rendering most decontamination useless. Symptoms usually appear within 15 to 30 minutes, although patients without significant respiratory symptoms at 4 hours are unlikely to show symptoms beyond this time frame. There is no antidote for nicotine toxicity.[60,63,64]

Direct-acting muscarinic agents produce excessive parasympathetic activity resulting in salivation, lacrimation, urination, diuresis, GI upset (including diarrhea), and emesis (often referred to as SLUDGE). Cholinesterase inhibitors, organophosphorus pesticides, and nerve agents produce a mixed picture of toxicity by binding and inactivating acetylcholinesterase to prevent normal termination of cholinergic stimulation at postsynaptic receptors.[65] In the PNS and CNS, the result is excessive nicotinic and muscarinic activity and, at the neuromuscular junction, depolarizing neuromuscular blockade. Over time the acetylcholinesterase becomes phosphorylated and weak hydrogen bonds change to covalent bonds, a process referred to as *aging*. Not all organophosphorus agents age at the same rate. Some nerve agents age within a few minutes, whereas some pesticides take as long as 72 hours to permanently inactivate the cholinesterase—activity is then only restored by synthesis of new enzyme.[55,65] Conversely, carbamates reversibly bind acetylcholinesterase, and this enzyme/chemical complex undergoes spontaneous hydrolysis, generally restoring cholinesterase function within hours. Furthermore, carbamates do not penetrate the CNS well, so central manifestations are usually less severe.[55] Because both organophosphates and carbamates cause bronchorrhea, bronchospasm, decreased respiratory drive, and paralysis of the muscles involved in breathing, death results from respiratory failure.[66,67] With dermal exposure, initial local hyperhidrosis is followed by systemic effects once the agent is absorbed, but with inhalation, upper airway manifestations and respiratory distress occur rapidly. Following ingestion, drooling and vomiting are the early signs of toxicity.

Atropine is used to reverse the muscarinic effects of cholinergic toxicity, whereas an oxime is provided to reverse neuromuscular blockade, and benzodiazepines to

treat seizures. Extremely large doses of atropine are provided to resolve bronchorrhea; tachycardia and pupil size are not indicative of an end point of atropine therapy.[66,67] Tachycardia during therapy is limited and not life threatening, and even patients with initial tachycardia should receive atropine to address pulmonary secretions, and with some agents, repeated doses or a constant infusion should be considered.[66,67] Oximes prevent cholinesterase aging. Pralidoxime is the oxime available and indicated for organophosphate poisoning in North America. The use of an oxime in conjunction with atropine is “atropine-sparing”—reactivation of affected cholinesterases decreases the amount of atropine necessary to combat life-threatening symptoms. Pralidoxime is generally not indicated in carbamate overdose because of its more limited toxicity.[56] Benzodiazepines should be considered for seizure prophylaxis.[66] Cholinesterase levels are not available in real time and should not be used to guide therapy when they will delay treatment.

Methemoglobinemia

In hemoglobin, oxidization of iron from the ferrous (2+) to the ferric (3+) state results in the formation of methemoglobin, an abnormal hemoglobin unable to transport oxygen. By shifting the oxygen saturation curve to the left, it decreases off-loading of any bound oxygen at the tissue level.[68] Box 128.6 lists xenobiotics that may cause oxidative stress and result in methemoglobinemia. Methemoglobin maintains a darker hue than deoxyhemoglobin, so the patient looks cyanotic in color, but it does not improve with oxygen administration—the blood may have a chocolate color, even after exposure to oxygen. Multiple-wavelength co-oximetry must be used to diagnose methemoglobin because standard pulse oximetry, used to measure oxy- and deoxyhemoglobin, cannot reliably assess the degree of methemoglobinemia and may overestimate or underestimate true oxygen saturation, generally reading in the 75% to 80% range as the methemoglobin level increases.[69,70] Methemoglobinemia should be suspected in a patient who appears cyanotic but has a normal partial pressure of oxygen.

Box 128.6

Toxins That Cause Methemoglobinemia

Benzocaine

Dapsone

Inhaled nitric oxide

Lidocaine

Naphthalene (found in certain mothballs)

Nitrates

Nitrites

Nitroprusside

Phenazopyridine

Prilocaine

Sulfonamides

Patients may appear blue with methemoglobin concentrations as low as 15 g/L, but a decision to treat is based on clinical symptoms, not the level. Treatment is not always necessary. Anemic patients have less hemoglobin to convert to methemoglobin, limiting their cyanotic appearance, but because this is usually a larger percentage of their functioning hemoglobin, they are more likely to express symptoms of hypoxia at lower methemoglobin levels.[68] Treatment begins with the administration of 100% oxygen (to maximize oxygen-carrying capacity by assuring that unaffected hemoglobin is fully saturated). If necessary, this is followed by intravenous methylene blue at a dose of 1 mg/kg. Methylene blue accelerates reduction of the oxidized heme iron of methemoglobin to its normal state via nicotinamide adenine dinucleotide phosphate (NADPH)–dependent methemoglobin reductase. Response is rapid, generally within 30 minutes. Depending on the inciting agent, as in the case of dapsone, recrudescent methemoglobinemia may require repeated doses of methylene blue. The total dose should not exceed 7 mg/kg because methylene blue is itself oxidizing and may cause additional methemoglobinemia or precipitate hemolysis. Methylene blue may be ineffective in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and may increase the risk of hemolysis or methemoglobinemia in this population. In patients not responding to methylene blue, G6PD deficiency should be suspected. In nonresponding patients who are severely ill, exchange transfusion should be considered.[68,71]

Xenobiotic-Induced Hyperthermia

In addition to the previously described syndromes, sympathomimetic and anticholinergic, three distinct xenobiotic-induced hyperthermic syndromes deserve attention. Distinctions of malignant hyperthermia, serotonin syndrome, and neuroleptic malignant syndrome are provided in Table 128.1. Although differences exist, there is also potential for overlap, and diagnosis may be difficult when no previous patient history is available. In all cases of severe hyperthermia, other causes such as sepsis should be ruled out. Because hyperpyrexia in these scenarios is not hypothalamic in origin, antipyretics are ineffective.

TABLE 128.1

Differences Between Drug-Induced Hyperthermia Syndromes

Syndrome	Causative Agent	Timing of Onset	Treatment
Malignant hyperthermia	Depolarizing neuromuscular blockers or inhalational anesthetics	Minutes	Dantrolene
Serotonin syndrome	Coadministration of two or more serotonergic agents	Hours	Supportive care, cyproheptadine
NMS	Antipsychotic drugs	Days	Supportive care,

			bromocriptine

Malignant hyperthermia, a genetically determined condition, results in rigidity and muscle damage following exposure to depolarizing neuromuscular blocking agents (succinylcholine) or inhalational anesthetic agents. This life-threatening condition of ryanodine receptor dysfunction results in excessive intracellular calcium in somatic cells and therefore persistent muscle rigidity. Along with aggressive cooling, dantrolene should be administered without delay. Dantrolene allows muscle relaxation through blockade of calcium release from the sarcoplasmic reticulum.[72]

Serotonin syndrome is a constellation of features resulting from excessive serotonergic activity in the CNS, most commonly associated with therapeutic regimens of two or more drugs that increase CNS serotonin transmission by different mechanisms. In addition to hyperpyrexia, hallmark features are altered mental status, excessive muscle activity, and autonomic instability. Suggested diagnostic criteria include a history of exposure to a serotonergic agent(s) and the presence of three of the following: mental status change, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhea, incoordination, or fever.[73] As opposed to other hyperthermic syndromes, it is distinguished by lower limb rigidity and hyperreflexia.[72,74] Symptoms, starting within hours of exposure, are short lived, and mild cases of serotonin toxicity are self-limiting; however, patients with severe toxicity may develop extreme hyperthermia and rhabdomyolysis with renal failure and cardiovascular collapse. Supportive treatment includes withdrawal of all serotonergic agents, benzodiazepines for muscle overactivity, and aggressive cooling. The use of cyproheptadine has been proposed as a serotonin antagonist at doses from 16 to 32 mg divided up to four times daily.[75-77] In cases of severe hyperthermia, cyproheptadine will do little to prevent further symptoms and should be abandoned for more aggressive therapy with cooling in addition to benzodiazepines or barbiturates and muscle paralysis with a nondepolarizing paralytic.

Neuroleptic malignant syndrome (NMS) encompasses a constellation of features triggered by exposure to neuroleptic drugs (phenothiazines, butyrophenones, atypical antipsychotics). It most commonly occurs after initiation of therapy or with a dose escalation; it has also been triggered by adding a serotoninergic agent to an established antidopaminergic agent and after withdrawal of dopaminergic agents used to treat Parkinson disease.[78,79] Onset is insidious, occurring over several days. Diagnosis requires exposure to a neuroleptic drug, fever, muscle rigidity, and at least two of the following: mental status change, mutism, tachycardia, labile blood pressure, diaphoresis, dysphagia, tremor, incontinence, leukocytosis, or elevated creatinine kinase.[80] Muscle rigidity, often described as lead pipe, is greater in the upper extremities. Although distinguishing NMS from lethal catatonia may be difficult, NMS may, arguably, represent the extreme end of the spectrum of extrapyramidal side effects of antidopaminergic medications. Unlike its milder counterparts, it is unresponsive to centrally acting anticholinergic agents; diphenhydramine and benztropine have no role in the treatment of NMS. Therapy is supportive and includes sedation and administration of benzodiazepines to address muscle rigidity. In severe cases, neuromuscular blockade with a nondepolarizing paralytic agent and active cooling may be required, whereas the addition of propofol or a barbiturate may decrease heat production through a decrease in metabolism.

Myoglobinuria and renal failure may complicate the course, and an elevated creatine kinase (CK) is consistent with the diagnosis of NMS. Both dantrolene and bromocriptine, a dopamine receptor agonist, have each been advocated for the treatment of NMS, but their effectiveness in this scenario is debated.[81,82]

Metabolic Acidosis With Increased Anion Gap

Anion gap metabolic acidosis (AGMA) is a laboratory toxidrome that presents a substantial differential diagnosis including many nontoxicologic causes (diabetic ketoacidosis, uremia, lactic acidosis, and inborn errors of metabolism to name a few). Agents most commonly associated with AGMA are represented by the acronym *MUDPILES,* listed in Box 128.7. Any agent causing shock will increase lactate and cause metabolic acidosis with an increased anion gap. It should be noted that although metabolic acidosis from toxic agents is generally associated with an increase in anion gap, a nonanion gap acidosis may be seen with the therapeutic use of carbonic anhydrase inhibitors, acetazolamide and topiramate, or from toxins that cause renal tubulopathy with chronic use such as toluene (an agent seen commonly with inhalant abuse).[83,84]

Box 128.7

Causes Anion Gap Metabolic Acidosis (MUDPILES)

M—Metformin, methanol

U—Uremia

D—Diabetic ketoacidosis (DKA), alcoholic ketoacidosis (AKA)

P—Phenformin, paraldehyde, propylene glycol

I—Iron, Isoniazid

L—Lactate (carbon monoxide, cyanide, etc.)

E—Ethylene glycol

S—Salicylates, solvents

Methanol and ethylene glycol, *toxic alcohols* found in various automotive antifreeze products and as chemical reagents, should be considered in cases of AGMA where the cause is unknown. Although ethylene glycol–containing antifreeze products contain fluorescein, which glows under a Wood's lamp, this is not a reliable method to screen for ingestion; even in the absence of fluorescein, fluorescence has been shown with hospital tubing and plastic containers and in the urine of most hospitalized pediatric patients in one study.[85,86] Laboratory analysis of blood should be done to provide a reliable diagnosis.

Toxic alcohols can cause CNS depression, although they have little toxic effect in their parent form. Toxic alcohols are metabolized first by alcohol dehydrogenase and

then aldehyde dehydrogenase to form toxic metabolites. Formic acid, resulting from methanol metabolism, precipitates severe metabolic acidosis and retinal toxicity described as “snowstorm blindness.” A number of toxic intermediates are formed from metabolism of ethylene glycol, but the end product, oxalate, results in severe metabolic acidosis, renal failure, and hypocalcemia through binding of oxalate to calcium to form crystals.[87]

Alcohols are osmotically active and will increase serum osmolality and the osmolar gap. An elevated gap suggests toxic alcohol poisoning, but a normal result does not exclude it because the gap depends on how much of the parent compound has been metabolized.[88,89] Over time, the anion gap increases consistently with metabolite production. As the parent compound is further metabolized the osmolar gap decreases and may be normal in patients presenting with symptoms of toxicity. Hemodialysis is indicated for toxic alcohol levels greater than 50 mg/dl and in severely toxic patients to eliminate toxic metabolites and correct metabolic abnormalities even when the parent compound is no longer detectable.[83]

To limit further generation of toxic metabolites, alcohol dehydrogenase must be blocked, and this can be achieved with either fomepizole or ethanol.[90,91] Fomepizole is the agent of choice and if a toxic alcohol is suspected, even if not yet confirmed, it should be provided at a loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours. The dose must be increased to 15 mg/kg after 48 hours because fomepizole induces its own metabolism. Fomepizole is dialyzable, so the dose must also be adjusted during hemodialysis.[92] Ethanol, maintained at levels greater than 100 mg/dl, will block metabolism of toxic alcohols through competition at alcohol dehydrogenase, which has a higher affinity for ethanol than methanol or ethylene glycol, but because ethanol infusions are difficult to compound safely, oral ethanol or ethanol via nasogastric tube is recommended. Ethanol, as an antidote, requires frequent blood alcohol measurements and carries the risks of inebriation, CNS depression, hypoglycemia, and hypotension.[91] If fomepizole is unavailable, ethanol must be used.

Although *iron* is an etiology for AGMA, the unmeasured anion here is lactate.[83,84] Iron is available alone and in combination with other vitamins, but iron salts have different proportions of elemental iron and care should be used when calculating an ingested dose. The first phase of iron toxicity consists of GI manifestations, vomiting and diarrhea, with possible hematemesis and hematochezia. Fluid and electrolyte losses can be severe and require aggressive resuscitation. The second phase, or so-called latent period, is a “quiescent” phase where GI symptoms have ceased but the patient feels unwell, often with tachycardia and an anion gap metabolic acidosis. Beyond 12 hours, the third phase exhibits symptoms progressing to cardiovascular collapse and shock, and the fourth phase is defined by fulminant hepatic failure. The corrosive effect of iron on the GI tract often results in scarring and stricture.[93] Doses higher than 20 mg/kg of elemental iron reliably produce GI irritation, although systemic toxicity is generally not seen with doses lower than 60 mg/kg. Absence of a prodromal GI phase within 4 hours of ingestion generally precludes serious systemic iron toxicity.[93]

Activated charcoal does not adsorb iron and whole-bowel irrigation should be considered if iron tablets remain in the GI tract, as evidenced by plain radiographs of the abdomen, although multivitamins, children's preparations, and liquid preparations may not be visible.[94] Serum iron levels should be measured within 6

hours of ingestion before significant redistribution to tissues. Total iron-binding capacity, used in the evaluation of chronic iron overload, may be falsely elevated in acute iron ingestion and should not be used in making treatment decisions.[92] Chelation via deferoxamine is indicated for serum levels higher than 500 μg/dL or signs of circulatory failure.[94] Intravenous dosing begins at 15 mg/kg/h via continuous infusion, but if symptoms persist beyond 24 hours, the deferoxamine dose should be decreased or temporarily discontinued as its use beyond this time is associated with acute respiratory distress syndrome.[95] Although children's multivitamin preparations do not produce toxicity at the same iron content as adult preparations, prenatal vitamins, except those containing iron carbonyl, have led to extreme toxicity with minor ingestion.[96]

Carbon monoxide (CO) results from incomplete combustion of carbonaceous fuels including natural gas, fuel oil, gasoline, propane, and charcoal. CO is a complex poison that not only affects oxygen binding to hemoglobin but produces reactive oxygen species, increases nitric oxide (NO), and modulates ion channels, most notably in cardiac tissues.[97] It should be considered in the AGMA differential because, through its ability to cause tissue hypoxia, it may precipitate a lactic acidosis. CO binds with high affinity to oxygen-binding sites of hemoglobin and myoglobin and disrupts the transfer of oxygen from erythrocytes to mitochondria. CO also binds directly to mitochondrial cytochrome oxidase and interferes with electron transport and adenosine triphosphate (ATP) production. However, most neurologic sequelae result from displacement of nitric oxide from platelets, leading to an increased generation of the free radical peroxynitrite. It is also this increase in NO that contributes to vasodilation and hypotension. Due to the potential for arrhythmias, serial ECG analysis should be performed. CO is not detected via standard pulse-oximetry, so analysis is through multiple-wavelength co-oximetry. Serial CO levels are not required with appropriate oxygen therapy as it will reliably decrease over time, with the exception of methylene chloride, whose metabolism leads to endogenous production of CO.

Correlation of CO level to symptoms is poor, largely because tissue effects are due to oxidative stress and ion channel effects. However, low levels of CO cause nonspecific symptoms (fatigue, malaise, nausea, and headache), whereas higher concentrations lead to impaired cognition and coma. Hypotension and syncope are significant effects that warrant aggressive treatment regardless of CO level; these events more commonly precede delayed or persistent neurologic sequelae.[97]

Controversy surrounding the treatment of CO poisoning remains. Therapy has always been centered on provision of oxygen to accelerate CO dissociation from hemoglobin. The half-life of CO under various oxygen concentrations is listed in Table 128.2. Hyperbaric oxygen (HBO), the administration of oxygen at supra-atmospheric pressure, has been advocated in the treatment of severe CO poisoning.[98] Although it accelerates the removal of CO from cytochrome oxidase, most CO has been eliminated from the blood by the time the patient is placed in the chamber. The benefits likely result from the reduction of leukocyte adhesion to endothelium.[99] It is proposed to decrease the incidence of delayed neurologic sequelae, although several studies exist with both positive and negative results, and unfortunately many are subject to bias and lack of controls.[98,100] Nonetheless, HBO should be considered when there is loss of consciousness, syncope, or persistent neurologic findings on exam (especially cerebellar dysfunction including ataxia with ambulation). HBO

treatment should be completed within 24 hours of exposure, but patients who experienced cardiac arrest should not be considered candidates.[65] Fetal hemoglobin has a higher affinity for CO, so neonates and fetuses may have higher than expected COHb levels, but no data on HBO therapy during pregnancy are available.

TABLE 128.2
Half-Life of COHb

Oxygen Concentration	Half-Life
21% (room air)	4-5 hours
100% (mask or endotracheal)	60-90 minutes
100% (hyperbaric molecular oxygen)	20-30 minutes

Cyanide is a highly toxic compound originating from a variety of sources. It is widely used as a reagent in industry, and several plants, including the seeds and pits of some fruits (eg, apples, cherries, peaches, and pears), contain cyanogenic glycosides that are converted to cyanide in the GI tract. The unapproved substance laetrile, sometimes used inappropriately to treat cancer outside the United States, is synthesized from amygdalin, a cyanogenic glycoside from peach pits. Enclosed fires, particularly those in which plastics or fabrics are combusted, can generate hydrogen cyanide (HCN) and, finally, iatrogenic cyanide poisoning results from the administration of nitroprusside; it is metabolized to cyanide and causes toxicity at high doses, after prolonged therapy without coadministration of sodium thiosulfate, or in the presence of renal failure.[101-104]

Cyanide rapidly produces toxicity when inhaled or when ingested. Cyanide salts are converted to HCN in the presence of gastric acid. Cyanide binds to cytochrome complex IV of the electron transport chain (cytochrome c oxidase) and inhibits oxidative phosphorylation, preventing ATP production. Nonspecific signs and symptoms reflect tissue hypoxia, and death may occur within minutes.[101] Venous oxygen levels are elevated because of the inability to use oxygen at the cellular level and therefore the patients do not appear cyanotic. Arterialization of the venous blood (an elevated pO_2) will result.

Treatment of cyanide poisoning involves immediate life support measures and antidote administration. Sodium nitrite and sodium thiosulfate are traditional antidotes for cyanide poisoning. Nitrites induce methemoglobinemia, which has a higher affinity for cyanide than cytochrome oxidase. Nitrites are potent vasodilators and can cause significant hypotension, best avoided by slow administration, although most significant vasodilation occurs in the most hypoxic tissues potentially providing therapeutic benefits. The initial pediatric dose is 0.2 mL/kg of a 3% solution. Excessive methemoglobinemia is a risk and the dose should be decreased in anemic patients. In fire victims who may have comorbid CO toxicity, the induction of methemoglobin may further reduce the already critically low oxygen-carrying capacity, although the timing of administration of antidotes and oxygen may reduce this risk. Sodium thiosulfate works via the mitochondrial enzyme rhodanese to produce the nontoxic thiocyanate that is excreted in urine. Sodium thiosulfate is used with or without sodium nitrite and can be administered early in patients with significant CO levels because it will not affect hemoglobin. Although it can cause hypotension, this is usually related to the rate of administration and it has a minimal adverse effect profile. Hydroxocobalamin, used to treat fire victims in

France for several years, is now available in the United States.[104,105] This cobalt-containing molecule interacts with cyanide to become cyanocobalamin (vitamin B_{12}), which is then eliminated in urine. Although effective, patients may experience hypertension after administration, and both their skin and body fluids will exhibit a reddish hue that interferes with several important colorimetric assays needed for patient monitoring. Severe acne has been reported 1 to 2 weeks after administration.[105] Pediatric administration is 70 mg/kg administered over 30 minutes (IV push is acceptable in severe toxicity). A second dose may be administered if necessary over a total administration time of 6 to 8 hours. The onset of action of hydroxocobalamin is more immediate than sodium thiosulfate, but because hydroxocobalamin must be reconstituted slowly over 20 minutes, time to onset of action is likely not different between the two antidotes. Although these two medications are synergistic, they must be administered in separate lines.[106,107] Published reports indicate that after the effect of hydroxocobalamin has ceased, sodium thiosulfate is still active, providing prolonged benefit.[108]

There are several forms of *salicylate,* the most common of which is acetylsalicylic acid (ASA), or aspirin. The most potent form is wintergreen oil, which is 98% methyl salicylate. Other forms include bismuth subsalicylate, sodium salicylate, and magnesium salicylate. Doses up to 100 mg/kg are likely to produce minimal toxicity, whereas doses above 300 mg/kg will have serious consequences, including death.

Early signs of salicylate toxicity include an increase in minute ventilation (primary respiratory alkalosis), tinnitus, nausea, and vomiting, but a hallmark of toxicity is a mixed-picture respiratory alkalosis and metabolic acidosis from uncoupling of oxidative phosphorylation and inhibition of the tricarboxylic acid cycle. This is nearly pathognomonic and warrants obtaining a salicylate level for evaluation. This uncoupling can lead to hyperpyrexia, and patients are often flushed and diaphoretic. Cerebral edema and pulmonary edema are potentially fatal complications but are more common with chronic toxicity rather than acute poisoning. Levels greater than 35 mg/dL produce minor symptoms, whereas significant signs of toxicity start to manifest at approximately 45 mg/dL after acute ingestion. Patients with chronic exposure will have severe symptoms at much lower levels (approximately 30 mg/dL).

Urinary alkalinization enhances elimination of salicylates and is accomplished by administration of sodium bicarbonate. Urinary pH should be monitored frequently to adjust the rate of bicarbonate infusion to achieve a urine pH above 7.5. Serum pH should be periodically monitored to avoid serious alkalemia and pH >7.55. Serum potassium and magnesium should be maintained within the normal range because to retain potassium in the presence of hypokalemia, protons are pumped into urine, defeating the process of urinary alkalinization. A bolus of dextrose may be warranted in patients with depressed sensorium, even if serum glucose levels are normal, as CNS glucose may be significantly lower than serum.[109] Hemodialysis is considered in patients with significant CNS alteration or salicylate levels greater than 70 mg/dl, as it effectively removes free salicylate in the toxic range. Additional indications for hemodialysis include renal impairment, volume overload, pulmonary edema, and severe electrolyte or acid-base abnormalities.

Toxin-Induced Seizures

It has been estimated that over 6% of new onset seizures result from exposure to a drug or toxin, and this may actually account for 9% of cases of status epilepticus.[110] Toxin-induced seizures result from several mechanisms including loss of inhibition via GABA, increase in CNS excitation through glutamate and NMDA receptors, sodium channel blockade, increased excitatory activity via norepinephrine release, excess cholinergic stimulation, adenosine antagonism, histamine antagonism, and metabolic disturbances.[111] In multiple reviews of seizure incidence, antidepressants account for the highest percentage of toxin-induced seizures, with bupropion exposures representing a disproportionate one-fourth of this population.[110] Seizures from tricyclic antidepressants (TCAs) have decreased with decreasing exposures, but other antidepressants including venlafaxine and citalopram are responsible for a considerable number.[112] Other concerning agents include tramadol, diphenhydramine, and antipsychotics. The incidence of amphetamine-induced seizures was second only to those induced by bupropion, but they accounted for a higher proportion of mortality. See Box 128.8 for a list of seizure-inducing toxins.

Box 128.8

Toxins That Commonly Induce Seizures (OTIS CAMPBELL)

O—Organophosphates

T—Tricyclic antidepressants

I—Isoniazid, insulin

S—Sympathomimetics

C—Camphor, cocaine

A—Amphetamines, anticholinergics

M—Methylxanthines

P—Phencyclidine (PCP)

B—Benzodiazepine withdrawal, botanicals

E—Ethanol withdrawal

L—Lithium, lidocaine

L—Lead, lindane

Toxin-induced seizures are global in nature and, unlike many forms of epilepsy, do not emanate from an irritable focus. For this reason, phenytoin and fosphenytoin are rarely effective and in some instances (theophylline and methylxanthines) have been suggested to increase seizure risk.[111] Management of toxin-induced seizures rarely changes based on the agent and relies on the administration of a

benzodiazepine for initial therapy. If proved ineffective, propofol or barbiturates are considered as second-line medications.

Isonicotnyl hydrazine (INH), or isoniazid, stands out among seizure-inducing agents as its mechanism is unique. INH, as well as other hydrazines including monomethyl hydrazine (MMH), interferes with pyridoxine metabolism. The decarboxylation of GABA to glutamate relies on pyridoxal-5-phosphate as a cofactor for glutamic acid decarboxylase. Without this active form of B6, GABA is depleted and excess glutamate leads to unchecked excitation in the CNS. INH both inhibits pyridoxine phosphokinase, required to convert pyridoxine to pyridoxal-5-phosphate, and reacts with pyridoxal-5-phosphate to form an inactive metabolite. Because hydrazine-induced seizures result from the depletion of GABA, they are difficult to control with usual anticonvulsant therapy. Treatment of INH poisoning is with pyridoxine, administered in a dose equal to the ingested dose of INH (by weight). If the dose ingested is unknown or the exposure is a result of MMH from *Gyromitra* mushroom ingestion, 5 g or 70 mg/kg in pediatric patients is a reasonable empiric starting dose. Benzodiazepines may work synergistically with pyridoxine, and barbiturates may also be considered in refractory cases.[111] When seizures are not controlled by these measures, a nondepolarizing paralytic should be applied to stop muscle contraction, although, in this case, EEG monitoring is critical to check for continued seizure activity in the brain.

Strychnine is a highly toxic rodenticide that produces convulsions through antagonism of postsynaptic glycine receptors that predominate in the spinal cord.[111] Although myoclonic activity is present, patients do not experience a postictal phase and these are not true seizures. Stimulation worsens muscular contraction, including the diaphragm, and mortality is often a result of hypoxia and hypoventilation. Activated charcoal binds strychnine in a 1 : 1 ratio and should be considered for decontamination. In addition to reducing unnecessary stimulus, the same algorithm for toxin-induced seizures applies here, as there is no known antidote.[111]

Cardiovascular Agents

Sodium channel blockade is a common conduction abnormality associated with poisoning. TCAs are a prime example where the electrocardiogram provides more information about the severity of toxicity and prognosis than actual drug levels. Blocking fast sodium channels in cardiomyocytes slows the rate of depolarization and is characterized by a wide QRS. In a landmark study of TCA overdose, it was proposed that a QRS >100 msec was correlated with an increased risk of seizures and QRS >160 msec was associated with a significant risk of arrhythmias.[113,114]

Severe toxicity occurs early in the course of TCA poisoning. Patients who do not manifest QRS widening, conduction abnormalities on ECG, altered mental status, seizures, or hypotension within the first 6 hours can be classified as low risk and no longer need pediatric intensive care unit monitoring.[113] Anticholinergic manifestations should be treated supportively only. Seizures should be treated with benzodiazepines. If the patient has coingested benzodiazepines, then flumazenil, a benzodiazepine receptor antagonist, should not be administered because it may unmask TCA-induced seizures. Widening of the QRS complex (>100 msec in adults) or ventricular arrhythmias should be treated with sodium bicarbonate to produce alkalinization of the serum. Bicarbonate is given in boluses of 1 to 2 mEq/kg until

ECG improvement is seen (narrowing of the QRS). Recurrence of QRS widening may be treated in the same manner. Alternatively, a bicarbonate infusion can be started after the initial bolus to maintain alkalemia (with monitoring to prevent over-alkalinization [ie, pH >7.55]). If bicarbonate continues to be infused, it may be stopped and the ECG monitored after approximately 6 hours of normal ECG tracings. Many newer antidepressants and antipsychotics, including bupropion, venlafaxine, and quetiapine, can manifest similar toxicity. Treatment for wide QRS associated with these substances is not different from that described earlier.

Calcium channel antagonists (CCAs) act on L-type calcium channels in the heart and vascular smooth muscle to block the influx of calcium resulting in negative inotropic, chronotropic, and dromotropic effects. CCAs also impair the release of insulin from the pancreas and in overdose, causing significant hyperglycemia.

Except in extremely large ingestions, dihydropyridines produce hypotension and reflex tachycardia, and in less severe poisoning, volume expansion alone may be sufficient. However, this is not true of other CCA classes. Intravenous calcium and vasopressors are indicated if hypotension remains refractory to intravenous fluids. Verapamil and diltiazem overdose are further complicated by pump failure, and these patients may benefit from inotropes such as dobutamine. Glucagon, which acts at a receptor other than the β receptor, increases cyclic adenosine monophosphate (cAMP) and has been reported to reverse refractory hypotension in CCA overdose (discussed in more detail later).

High-dose insulin/euglycemia therapy has been shown effective in several successful animal models and case reports and case series to reverse cardiogenic shock associated with CCA overdose; this therapy has become commonplace in this setting.[115-117] The recommended dose is from 0.5 to 1 unit/kg of insulin as a bolus, followed by an infusion titrated to efficacy. Administration of dextrose should proceed concurrently, and serum glucose concentration should be monitored at least hourly to detect hypoglycemia and adjust dextrose accordingly. Transcutaneous pacing in these patients is difficult but if successful, pacing should proceed at a low rate, near 60 bpm, to maximize filling time. Most patients continue to exhibit decreased contractility such that, even with pacing, adequate cardiac output may not be achieved, and patients who are unresponsive to medical management should be considered for a left ventricular assist device (L-VAD) or extracorporeal life support (ECMO).

β-Adrenergic antagonists comprise a fairly extensive list of therapeutic agents that are largely distinguished from each other by their selectivity (or lack thereof) for the β_1 receptor. Atenolol, metoprolol, esmolol, and acebutolol are β_1-selective agents, whereas agents such as propranolol, nadolol, and pindolol act both at β_1 and β_2 receptors. Propranolol is unique in that it is highly lipophilic and has sodium channel–blocking activity and can additionally precipitate seizures and coma at toxic doses. The β_1 receptors are largely found in the heart and agonism causes positive inotropic and chronotropic effects; β_2 receptors are found in the airway smooth muscle, where they cause bronchodilation; in the small blood vessels, where they cause vasodilation; and in several other organs, where they have a number of effects that are less important in the context of poisoning.

Acute β-adrenergic antagonist overdose results in bradycardia, hypotension, and conduction delay, although toxicity is generally much less severe than with CCAs.

Bronchospasm may occur in susceptible individuals. Hypoglycemia has been reported in children with overdose of drugs in this class, although it has also been seen with therapeutic use of propranolol.[118,119] Monitoring alone may be sufficient if the only manifestation is asymptomatic bradycardia. Patients with bradycardia and hypotension may respond to atropine, although they are expected to have initial decreased vagal tone. β-Agonists have variable effects in the presence of β-adrenergic blockade. In theory, mixed agonists could worsen hypotension by causing β_2 receptor–mediated vasodilation. The phosphodiesterase inhibitors amrinone and milrinone have a theoretic benefit of improving contractility by blocking the breakdown of cAMP but have not been shown to be more effective than glucagon.[120,121] Glucagon acts by a nonadrenergic receptor to increase intracellular cAMP and improve cardiac contractility. The suggested dose is a 0.15 mg/kg intravenous bolus followed by an infusion of 0.05 to 0.1 mg/kg/hr, although no maximum dose has been determined.[117] Seizures should be treated with benzodiazepines as first-line therapy, and bronchospasm may respond to anticholinergic agents if inhaled β_2-agonists fail to overcome the β-blockade. Like CCAs, patients not responding to appropriate therapy should be evaluated for LVAD or ECMO.

Digoxin and related digitalis glycosides block the sodium-potassium adenosine triphosphatase (Na/K-ATPase) pump resulting in increased intracellular calcium and improved contractility as well as increased vagal tone and sinoatrial (SA) and atrioventricular (AV) node depression. In overdose, sympathetic tone is increased and may lead to increased automaticity.

Symptoms of toxicity include nausea, vomiting, lethargy or confusion, and cardiac dysrhythmias. Although virtually every rhythm has been described in digoxin toxicity, bidirectional ventricular tachycardia and atrial tachycardia with AV block are characteristic. Blockade of Na/K-ATPase causes hyperkalemia, and levels greater than 5.5 mEq/L have been associated with a high risk of mortality.[122] Poisoning is confirmed with serum digoxin levels, although because of a long distribution phase, the serum level may not accurately reflect tissue levels until at least 6 hours after ingestion.

Sinus bradycardia or heart block may respond to atropine alone but more serious arrhythmias are an indication for treatment with digoxin-specific Fab fragments (eg, Digibind, DigiFab). Drugs that further depress the SA or AV node should be avoided. Hyperkalemia resolves with Fab fragment therapy as it restores function of the Na-K pump. Because digoxin causes intracellular hypercalcemia, administration of calcium could theoretically increase toxicity.[123] Fab fragment therapy in children is indicated with a strong history of ingestion of at least 0.1 mg/kg of digoxin, level greater than 5 ng/mL, rapidly progressing signs and symptoms of digoxin toxicity, potentially life-threatening arrhythmias, or a serum potassium level greater than 5.5 mEq/L.[124]

A clinical picture similar to digoxin poisoning may be seen with the ingestion of cardiac glycoside-containing plants (oleander, fox glove, lily of the valley, etc.). Cardiac glycoside poisoning may cross-react with the digoxin immunoassay and may respond to Fab fragment therapy.[124] However, an antidote dose cannot be calculated from this level, so dosing should be empiric in this situation.

Acetaminophen (Paracetamol)

Although it does not cause a toxidrome per se, acetaminophen is the most commonly ingested drug in intentional overdose and it may cause fulminant hepatic failure and therefore admission to the pediatric intensive care unit. Major routes of elimination of acetaminophen are through glucuronidation or sulfation followed excretion in the urine. A minor pathway is via CYP2E1 to produce *N*-acetyl-p-benzoquinone-imine (NAPQI), a toxic metabolite capable of binding to hepatocytes and causing cell death. With therapeutic doses of acetaminophen, NAPQI is rapidly detoxified by glutathione. In overdose, larger amounts are formed and may overwhelm the available glutathione stores, resulting in a centrilobular hepatic necrosis.

Patients can initially present with nausea and vomiting, but more often they have no symptoms or signs, and laboratory detection is important because treatment is most effective if administered early after ingestion. Transaminases begin to rise at approximately 18 to 24 hours after ingestion and peak between 48 and 72 hours. Patients progress either to fulminant hepatic failure or to complete recovery. *N*-acetylcysteine (NAC) reduces the incidence of hepatotoxicity through several suggested mechanisms, including enhanced synthesis of glutathione and free radical scavenging.[125] Although it is most efficacious when administered within 10 hours of ingestion, studies have shown benefit when administered to patients presenting after this window of time. In one study, intravenous NAC decreased the risk of death from acetaminophen-induced fulminant hepatic failure, even in patients who presented with already established hepatic encephalopathy.[126] The decision to treat an acute ingestion is based on plotting a single acetaminophen blood level at least 4 hours after ingestion on the Rumack-Matthew nomogram (Fig. 128.1). Before 4 hours and after 24 hours, the nomogram is not useful. An acetaminophen level should be measured and liver function analyzed to assess the patient's risk for development of toxicity and potential prognosis. The nomogram has not been validated in chronic ingestion or multiple, staggered ingestions. In these cases, the nomogram should not be relied on for an assessment of toxicity. A poison control center should be consulted for specific treatment advice.

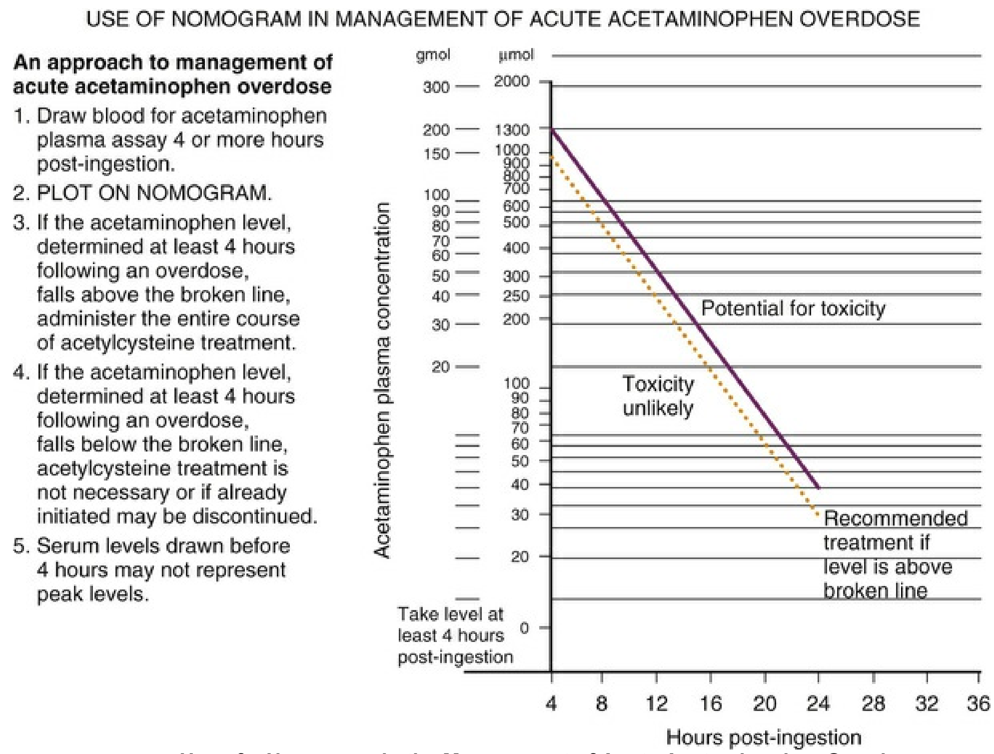

FIG. 128.1 **Use of a Nomogram in the Management of Acute Acetaminophen Overdose.**

SECTION XIII

Anesthesia Principles for the Pediatric Intensive Care Unit

OUTLINE

CHAPTER 129

Airway Management

Ann E. Thompson, Rosanne Salonia

PEARLS

- Safe management of the critically ill child's airway requires an understanding of the anatomic and physiologic changes that occur from birth through adolescence, recognition of congenital and acquired airway abnormalities, appreciation of the pathophysiologic consequences of airway manipulation, and preparation for airways that are potentially difficult to manage.
- Laryngoscopy and intubation are potent physiologic stimuli that are associated with severe discomfort, profound cardiovascular and cerebrovascular changes, and increased airway reactivity.
- Recognizing and preparing to manage a difficult airway are essential steps for the prevention of potentially lethal complications of intubation.
- The approach to intubation must be tailored to specific circumstances, such as a full stomach, elevated intracranial pressure, cervical spine injury, and upper airway obstruction.
- Alternative approaches to airway management, such as the lighted stylet, laryngeal mask airway, cricothyrotomy, retrograde intubation, and tracheostomy, as well as video laryngoscopy, may be lifesaving.

Accurate assessment and safe management of the airway of a critically ill child are the essential first steps in providing effective intensive care. They require understanding the anatomic and physiologic changes that occur from birth through adolescence, recognizing congenital and acquired airway abnormalities, appreciating the pathophysiologic consequences of airway manipulation and underlying disease processes, and preparing for airways that may potentially be difficult to manage.

Anatomic Considerations

The configuration of the child's airway changes dramatically from birth to adulthood (Fig. 129.1). The nose is the site of nearly half of the total respiratory resistance to airflow at all ages. The infant's nose is short, soft, and flat, with small, nearly circular

nares. The nasal valve, the narrowest portion of the nasal airway, approximately 1 cm proximal to the alar rim in newborns, measures only about 20 mm^2.[1,2] By 6 months, dimensions of the nares have nearly doubled, but they are still easily occluded by edema, secretions, or external pressure. Although an infant is perhaps not as much the obligate nose breather as commonly assumed, signs of airway obstruction frequently develop when the infant's nose is blocked.[3,4]

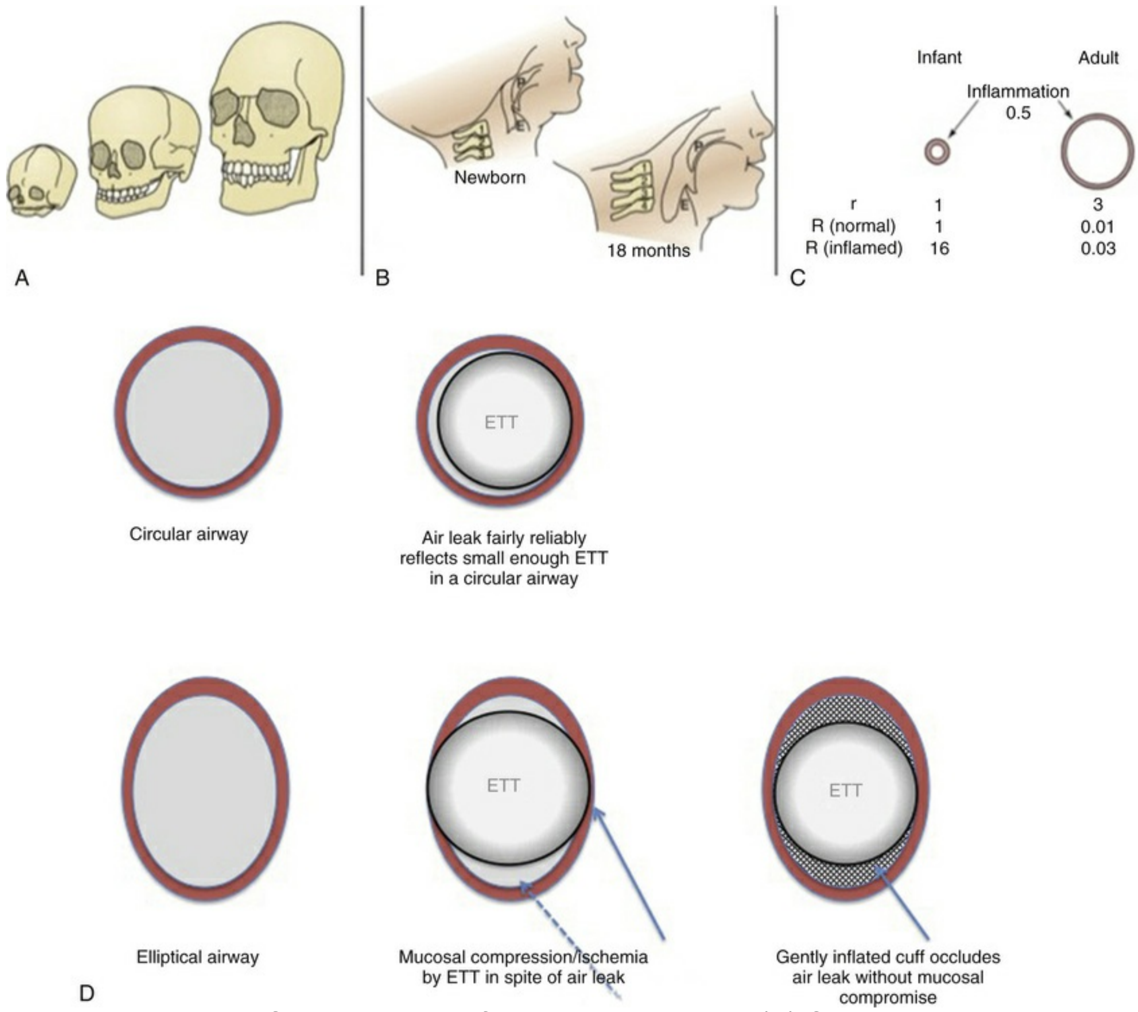

FIG. 129.1 Characteristics of the pediatric airway. (A) Changes in mandibular shape from infancy through adolescence. (B) The epiglottis is initially cephalad in infancy, then it descends throughout childhood. *E,* epiglottis; *P,* palate. (C) Edema has a much greater effect on airways resistance in the young child than later in life. *r,* relative radius of the trachea; *R,* relative airways resistance. (D) Contrary to traditional teaching, imaging indicates that the infant and young child's airway is slightly elliptical in shape, and its narrowest portion is at the vocal cords, as in adults. The elliptical shape raises questions about the value of an air leak in selecting the correct endotracheal tube (ETT) size; a leak may be present even in the presence of mucosal compression and ischemia. A gently inflated cuff seals the airway more effectively, but close monitoring of cuff pressure is necessary. The cricoid is the most rigid segment and may be most at risk of injury.

In infancy the mandible is small and the basicranium (which provides the roof of the nasopharynx) is flat, creating a small oral cavity. Over the years of its development, the jaw grows primarily down and forward, with the mandibular ramus increasing in height and width. The posterior portion of the basicranium develops a progressively more rounded configuration through childhood, which results in a larger nasal airway to meet the need for increased airflow (and provides a chamber for the resonance of adult speech).

Under normal conditions, the genioglossus muscle and other muscles of the pharynx and larynx help maintain airway patency. Both tonic and phasic inspiratory activity synchronized with phrenic contraction have been noted in animal and human studies. In particular, the genioglossus increases the dimensions of the pharyngeal airway by displacing the tongue anteriorly.[5] In the infant and young child, the tongue is large relative to the bony structures surrounding it and the cavities they form. Relatively little displacement is possible at any time, and loss of tone during sleep, sedation, or central or peripheral nervous system dysfunction is more likely than in older patients to allow the tongue to relax into the posterior pharynx and cause upper airway obstruction.

The infant larynx is high in the neck at birth, with the epiglottis at the level of the first cervical vertebra and overlapping the soft palate. This approximation of structures, in combination with the relatively large tongue and small mandible, probably contributes to the vulnerability to airway obstruction in infants and young children. By 6 months the epiglottis has moved to about the level of the third cervical vertebra and is separate from the palate. It continues to descend to its adult position at about the fifth or sixth cervical vertebra by early adolescence. The infant epiglottis is soft and omega shaped, in contrast with the more rigid, flatter adult structure, and it has greater potential to occlude the airway.

For many years standard teaching has been that immature larynx and trachea differ greatly from the mature structures. However, modern imaging techniques, including bronchoscopy, CT scanning, and MRI, provide evidence that contradicts previous dogma.[6-8] The immature larynx is roughly cylindrical, not funnel shaped, similar to the straight vertical column seen in adults. Although previously the narrowest part of the young child's airway was thought to be at the level of the cricoid cartilage, studies show that, as in adults, it is at or just below the vocal cords. Nonetheless, the cricoid is more rigid than other areas of the airway and vulnerable to injury. At all ages the trachea is slightly elliptical in cross section with the anteroposterior diameter slightly greater than the transverse diameter. These newer findings have important implications for endotracheal intubation.

The internal dimensions of the trachea in a newborn are approximately one-third those of an adult, and absolute resistance to airflow is higher in newborns than in older children and adults. Because the most important factor determining resistance (R) is the radius (r) of an airway (R proportional to $8\ l/r^4$), small changes in airway diameter in infants or young children as a consequence of edema or secretions have a far greater effect on resistance than similar changes in larger patients (see Fig. 129.1C).

Basic Airway Management

Airway management depends on a brisk assessment of the patient's breathing and

knowledge of the likely progression of the airway problem—that is, deterioration versus improving function. In virtually any setting in which respiratory difficulty is suspected, oxygen should be administered until the specific abnormality can be identified and adequately treated. Although extreme hypercarbia usually is well tolerated, hypoxia is routinely catastrophic and is not necessarily obvious on initial examination. From the alveolar air equation, it is obvious that hypercarbia produces hypoxia at low fractions of inspired oxygen (FiO_2) (Table 129.1). If the patient is breathing spontaneously, attention is directed first to signs of upper airway obstruction, including the absence of audible or palpable airflow, stertorous sounds, stridor, or a rocking chest and abdominal motion rather than the normal, smooth rise and fall that should occur with inspiration and expiration.

TABLE 129.1

Impact of Providing Supplemental Oxygen During Hypercarbia on Alveolar Oxygen Tension

Alveolar gas equation	$PaO_2 = FiO_2\ (PB - Ph_2o) - PaCO_2/0.8$
Room air, normocarbia	$PaO_2 = 0.21\ (760 - 47) - 40/0.8 = 99$ mm H_2O
Room air, hypercarbia	$PaO_2 = 0.21\ (760 - 47) - 80/0.8 = 50$ mm H_2O
Supplemental O_2, hypercarbia	$PAO_2 = 0.4\ (760 - 47) - 80/0.8 = 185$ mm H_2O

FiO_2, fraction of inspired oxygen; *PAO_2*, partial pressure of oxygen, alveolar.

An alert child with normal neuromuscular function usually instinctively assumes a body position that minimizes upper airway obstruction. However, a child with an altered level of consciousness or severe neuromuscular weakness may be unable to maintain a patent airway because of the inability to alter his or her position or maintain adequate glossopharyngeal muscle tone.

Nasopharyngeal Airway

A nasopharyngeal airway that extends through nasal passages to the posterior pharynx and beyond the base of the tongue often is adequate to relieve obstruction and is tolerated by most patients, even those who are conscious (Fig. 129.2). An airway of appropriate size extends from the nares to the tragus of the ear and is of the largest diameter that passes through nasal passages without causing blanching of the skin surrounding the nares. The airway tube should be well lubricated before placement. Risks of nasopharyngeal airways include nasal ulceration, bleeding, laceration of friable lymphoid tissue, rupture of a pharyngeal abscess, laryngospasm, and potential passage through the cribriform plate in patients with basilar skull fractures. Topical vasoconstricting agents reduce but do not eliminate the risk of bleeding. Like other nasal tubes, use of nasal airways increases the risk of sinusitis; therefore contraindications to their use include severe coagulopathy, cerebrospinal fluid (CSF) leaks, and basilar skull fractures.

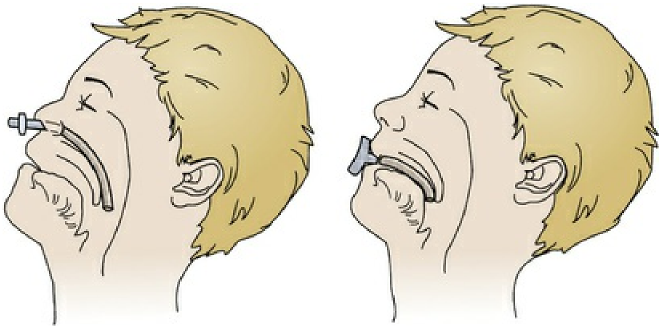

FIG. 129.2 Nasopharyngeal and oropharyngeal airways in good position.

Oropharyngeal Airways

Oropharyngeal airways displace the base of the tongue from the posterior pharyngeal wall and break contact between the tongue and palate (see Fig. 129.2). Size selection is important. An excessively long airway may encroach upon the larynx and cause laryngospasm. An airway that is too short may actually push the tongue posteriorly and exacerbate obstruction. If the airway is held at the side of the face with the flange just anterior to the incisors, the tip should be at or near the angle of the mandible. The airway should be positioned following the curve of the tongue while the tongue is held down and forward with a tongue depressor. Inserting the airway with its concave side facing the palate and then rotating it may traumatize the oral mucosa or damage teeth. Oral airways are poorly tolerated in any patient with a functional gag reflex and may induce vomiting. As a consequence, they are of little more than temporary value in the critically ill child. They may support a patent airway for bag-valve-mask ventilation in preparation for intubation.

Oxygen Delivery Devices

Nasal Cannulas

Nasal cannulas consist of two hollow prongs projecting from a hollow face piece. Humidified oxygen (100%) flows from a standard source, effectively delivering a pharyngeal concentration of 25% to 40% after mixing with variable amounts of room air. The cannulas are easy to use, often readily tolerated, lightweight, economical, and disposable and take advantage of the humidifying properties of the nasopharynx. Flow typically is limited to only 3 to 5 L/min because of the extent to which relatively dry gas flow cools and dries the nasal airway. The use of nasal cannulas is limited by the relatively low oxygen concentration that can be delivered. High-flow nasal cannulas can deliver up to 40 L/min of warmed, humidified gas and also are usually well tolerated, although the noise level for the patient can be high. The oxygen concentration delivered is higher than with simple nasal cannulas. High-flow nasal cannulas generate positive distending pressure similar to that provided by nasal continuous positive airway pressure. The pressure generated is dependent on the interaction among the flow rate, patient size, and anatomy of the patient's airway, but it is probably limited to 4 to 5 cm H_2O.[9,10] At least in infants, positive pressure generation requires a closed mouth.[11]

Masks

A variety of masks are available for delivering oxygen. Simple masks fit loosely. The oxygen concentration delivered varies, depending on the patient's inspiratory flow rate and the oxygen flow into the system. Partial rebreathing masks incorporate some sort of reservoir, usually a bag below the chin. Provided that flow into the system exceeds the patient's minute ventilation and that the bag does not collapse on inspiration, little carbon dioxide is inhaled, and concentrations of oxygen up to about 60% can be achieved. Non-rebreathing masks must fit snugly. They incorporate a mask, reservoir, and one-way valves that vent expired gas but do not permit inspiration of room air. As a result, they can deliver close to 100% oxygen.

Noninvasive Positive Pressure Ventilation

Continuous positive airway pressure (CPAP) delivers high concentrations of oxygen and maintains positive airway pressure in the spontaneously breathing patient. CPAP is applied with an oxygen source connected to either a tight-fitting nasal or full facemask or helmet in children or via nasal prongs in the neonate and older infant. CPAP offers the benefit of maintaining alveolar expansion and decreases work of breathing for many patients, particularly those with pulmonary parenchymal disease, as well as for some patients with airway obstruction related to poor upper airway tone or laryngeal-, tracheal-, or bronchomalacia.

Like CPAP, bilevel positive airway pressure (BiPAP) can be provided by mask, but it requires a ventilator to assist with flow delivery. The patient's inspiratory effort triggers the BiPAP machine to deliver decelerating flow in order to reach a preset pressure, defined as inspiratory positive airway pressure. When a patient's own inspiratory flow falls below a preset amount, ventilatory assistance ceases and maintains expiratory airway pressure at a predetermined value (typically between 5 and 10 mm Hg). Uses in the pediatric intensive care unit (PICU) include upper airway obstruction, atelectasis, exacerbations of neuromuscular disorders, support for mild to moderate respiratory failure, and as an assist in weaning patients from invasive mechanical ventilation.

Both CPAP and BiPAP offer the advantage of providing respiratory support without endotracheal intubation but require that the child tolerate a close-fitting mask. A more extensive discussion of CPAP and BiPAP is available in Chapters 57 and 58.

Establishing a Functional Airway

A patient who is apneic or in severe respiratory distress requires ventilation assisted initially with a bag and mask. Probably no skill is more important for the intensivist than the ability to provide effective manual bag-mask ventilation. It can be lifesaving while preparation for endotracheal intubation proceeds or when intubation cannot be accomplished. Effective technique requires positioning the patient adequately to open the upper airway, achieving a good mask-face seal, inserting an oral or nasal airway if needed, and generating an adequate tidal volume, coordinating manual breaths with patient efforts when they are present. Poor technique results in ineffective oxygenation and ventilation, gastric insufflation and distention, and increased risk of aspiration.

If the child is too weak or obtunded to maintain pharyngeal tone independently, the head should be placed on a thin cushion to cause slight cervical spine flexion and gentle extension at the atlantooccipital joint. In infants, the large occipitofrontal diameter makes the cushion unnecessary, although a thin pad under the shoulders may be useful. It appears that aligning the external auditory meatus with the sternal notch is a reasonable guide to appropriate positioning. Current recommendations are to avoid overextending the baby's flexible cervical spine, which may stretch and compress the trachea and potentiate, rather than relieve, obstruction. Studies have questioned the existence of this phenomenon but to date have included a small number of infants, all with normal airways.[12] Appropriate head tilt separates the tongue from the posterior pharyngeal wall. If airway obstruction persists, the chin can be pulled forward by encircling the mandible behind the lower incisors between the thumb and fingers. The most effective means of relieving functional obstruction is the so-called triple airway maneuver. With the fingers behind the vertical ramus of the jaw, the mandible is displaced downward, forward, and finally upward again until the mandible and lower incisors are anterior to the maxilla. This action effectively pulls the tongue forward and away from the pharyngeal wall.

In some patients, establishing a functional airway is sufficient to allow resumption of effective spontaneous ventilation. In other patients, steady positive airway pressure is necessary to overcome residual obstruction. If breathing remains inadequate, manual ventilation is necessary. Effective ventilation requires a good mask fit. The mask should sit smoothly on the bridge of the nose and the bony prominence of the chin. It is important to avoid airway occlusion with the mask or hand or pressure on eyes, soft nasal structures, or branches of the trigeminal and facial nerves. A good mask fit is predictably difficult in a patient without teeth, a flat or prominent nose, or micrognathia. Insertion of a nasal or oropharyngeal airway may help maintain an adequate airway. Once a good mask fit is ensured, ventilation may be assisted.

Two types of bags are in general use: self-inflating resuscitation bags and standard anesthesia bags. Because self-inflating bags vary substantially, specific directions for their use must be followed carefully. All bags incorporate an adapter to connect to a mask or endotracheal tube, a bag, a pressure-relief valve, and a port for fresh gas inflow. Most bags designed for children have pressure-relief valves designed to pop off at 35 to 45 cm H_2O pressure to prevent excessive volume delivery and subsequent barotrauma. In patients with poor compliance or increased airway resistance, it may be necessary to bypass this valve temporarily to provide effective ventilation. Most systems incorporate valves that prevent rebreathing. Fresh gas flows through the valve on spontaneous inspiration (negative pressure) or on creation of positive pressure by squeezing the bag (Fig. 129.3). Exhaled gas is vented to the atmosphere. Not all systems allow spontaneous breathing; those that do demand that the patient generate at least a little negative pressure, so a good mask fit is necessary. Holding the mask above the patient's face provides no supplemental oxygen. The percentage of oxygen delivered depends on the percentage of oxygen from the source, the fresh gas flow rate, and the respiratory rate, which determines the time available for the bag to refill. Most systems require some sort of reservoir assembly in addition to the self-inflating bag to prevent entrainment of room air. With a reservoir, 100% oxygen may be delivered; without a reservoir, most deliver less than 50%.

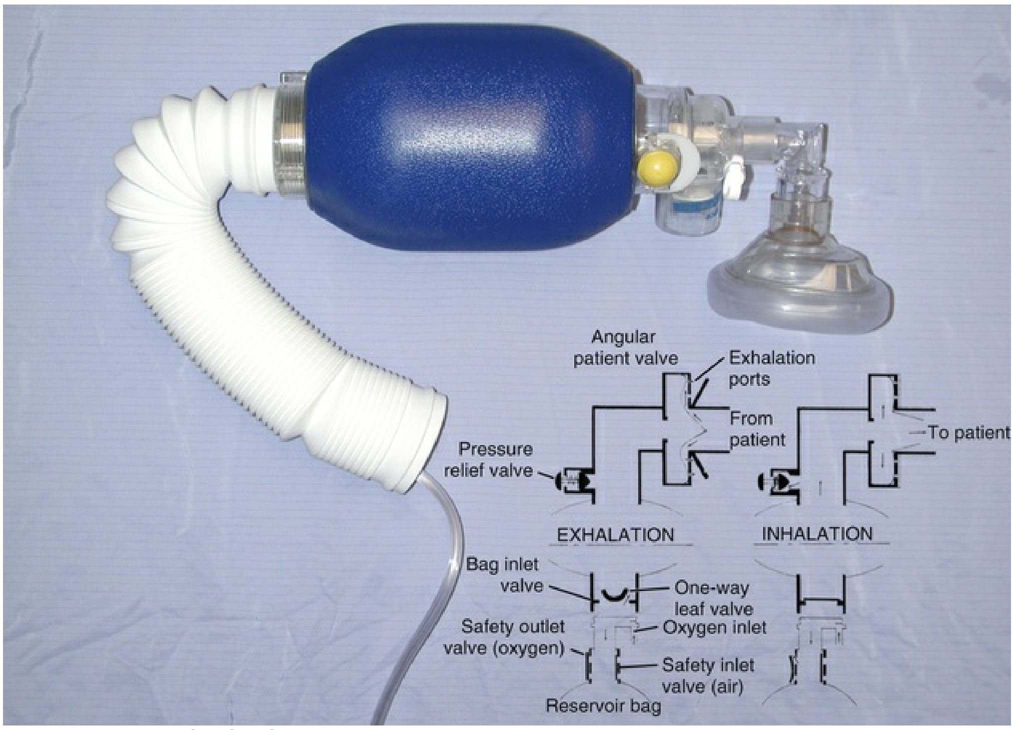

FIG. 129.3 Self-inflating manual ventilation bag with tubing as a reservoir. *(Inset)* Function of one type of valve, permitting manual positive pressure breathing, or spontaneous breathing, but requiring generation of negative pressure by the patient to open the valve. Simply holding the mask over the patient's face does not provide supplemental oxygen.

Anesthesia bags require flow from a source of gas under pressure in order to expand. Many variations have been reviewed extensively in the anesthesia literature. These circuits depend on the location of the fresh gas inflow and overflow valves, the rate of fresh gas flow, the respiratory rate, tidal volume, carbon dioxide production, and whether ventilation is spontaneous or controlled. Many ICUs use the Mapleson D configuration, with the fresh gas source attached just distal to the patient connection. The overflow valve is proximal to the reservoir bag. During expiration, the patient's exhaled tidal volume mixes with fresh gas flowing into the system and accumulates in the tubing and bag. With sufficiently high fresh gas flow, alveolar gas is washed to the overflow valve and eliminated from the circuit. The system requires higher fresh gas flow to avoid rebreathing during spontaneous ventilation than during controlled breathing, but a safe rule of thumb recommends fresh gas flow two to three times the minute ventilation. During controlled ventilation, a minimum of 100 mL/kg/min ensures that carbon dioxide elimination is proportional to minute ventilation.[13,14] At flows less than 90 mL/kg/min, increasing ventilation may only increase CO_2 rebreathing.

Endotracheal Intubation

The pediatric intensivist is frequently called upon to intubate critically ill patients when brief periods of ventilation with a bag and mask are inadequate to reverse the underlying disorder. Few of these intubations are performed under the optimal conditions commonly attainable in the operating room—that is, relatively healthy

children with empty stomachs who have previously been sedated and are intubated in a controlled environment with all members of the team experienced in and prepared for airway management. Instead, patients are often critically unstable and require intubation suddenly, often in settings where the procedure is not routine. Intubation often is viewed only as a means to an end, namely, mechanical ventilation. However, it is associated with profound physiologic consequences that may dramatically affect the patient. The intensivist's appreciation of these factors and ability to minimize the adverse physiologic consequence of airway manipulation may as decisively determine patient outcome as his or her skill in providing the intensive care that follows.

Indications

Respiratory Failure

Respiratory failure may result from dysfunction at any point along the ventilatory pathway. To provide appropriate support and to avoid hazards specific to the individual disorder, airway intervention must be tailored to the underlying cause. Outside the operating room, the need for intubation is most commonly associated with respiratory failure resulting from upper or lower airway or pulmonary parenchymal disorders that require mechanical ventilation. Respiratory failure is defined in terms of excessive work of breathing or inadequate oxygenation (in the absence of cyanotic congenital heart disease) or carbon dioxide elimination. Box 129.1 contains one set of criteria for intubation.

Box 129.1

Indications for Intubation

1. PaO_2 <60 mm Hg with fraction of inspired oxygen ≥0.6 (in absence of cyanotic congenital heart disease)
2. $PaCO_2$ >50 mm Hg (acute and unresponsive to other intervention)
3. Upper airway obstruction, actual or impending
4. Neuromuscular weakness

- Maximum negative inspiratory pressure ≥20 cm H_2O
- Vital capacity <12 to 15 mL/kg

5. Absent protective airway reflexes (cough, gag)
6. Hemodynamic instability (cardiopulmonary resuscitation, shock)
7. Controlled therapeutic (hyper)ventilation

- Intracranial hypertension
- Pulmonary hypertension
- Metabolic acidosis

8. Pulmonary toilet

9. Emergency drug administration

Hemodynamic Instability

Patients with hemodynamic instability often benefit from assisted ventilation. The need for controlled ventilation as a component of cardiopulmonary resuscitation is obvious. In addition, early intubation in anticipation of impending cardiovascular collapse may prevent catastrophic tissue hypoxia. Redistribution of blood flow away from respiratory muscles, especially the diaphragm, in patients with marginal cardiac output may improve perfusion of other vital organs, including the heart, and help prevent cardiac arrest.[15-19]

Neuromuscular Dysfunction

For additional information on neuromuscular dysfunction, see Chapters 49, 58, and 71.

Neuromuscular dysfunction or severe chest wall instability (or deformity) may cause failure of the bellows apparatus for breathing.[20] Initially, tidal volume remains normal or at least sufficient to maintain normal blood gas tensions, but vital capacity and maximal inspiratory and expiratory pressures decrease. Inability to take a deep breath or cough forcefully risks progressive segmental or lobar atelectasis, inability to clear secretions, bronchial obstruction, and possible major airway obstruction with sudden severe hypoxia or carbon dioxide retention. Increasing weakness results in progressively smaller tidal volumes, loss of upper airway tone, and, ultimately, inadequate minute ventilation. Bulbar dysfunction may lead to aspiration as a result of impaired swallowing and inadequate cough.

Measurement of ventilatory reserve provides a better assessment of the patient's need for ventilatory assistance than do arterial blood gas tensions alone. Maximum negative inspiratory pressure and vital capacity are two simple, commonly used tests for this purpose. A variety of other measures also help assess respiratory "strength," but most are difficult to perform in sick, uncooperative infants and children. Patients with diffuse neuromuscular weakness of any cause, spinal cord dysfunction above the level of T6, or loss of phrenic nerve or diaphragm function are particularly prone to respiratory failure.[21] Because of the extreme compliance of their chest walls and relative ineffectiveness of intercostal muscles, infants younger than approximately 6 months tolerate diaphragmatic paralysis poorly.[22-26]

Many patients with neuromuscular weakness respond well to noninvasive forms of ventilatory support.[20,27] Decisions about the best approach to airway management should be based on the nature and likely progression of the illness, the child's maturity and level of consciousness, and the timing of the onset of respiratory

insufficiency. In an emergency, endotracheal intubation is likely to be safest, with transition to noninvasive support when careful planning allows.[27]

Failure of Central Nervous System Regulation of Ventilatory Drive

Failure of central nervous system regulation of ventilatory drive may prompt intubation (see Chapter 47). Centrally mediated hypoventilation is manifest as CO_2 retention, usually in the absence of increased work of breathing. On occasion the decision to support ventilation may be based on observing abnormal ventilatory patterns in anticipation of neurologic deterioration. Loss of protective airway reflexes, including the cough and gag reflexes, can result from central nervous system depression, cranial nerve abnormalities, or severe motor weakness. In such patients, intubation is indicated to prevent aspiration. Intubation may be appropriate in anticipation of the need to protect the airway and support ventilation during deep sedation for procedures or diagnostic studies.

Other Indications

Intubation is indicated as a step toward therapeutic controlled (hyper)ventilation (eg, in patients with increased intracranial pressure [ICP] or pulmonary hypertension) or to support spontaneous hyperpnea in patients with metabolic acidosis and other conditions. Patients with profuse, thick, or tenacious secretions (eg, as a result of bacterial pneumonitis or smoke inhalation) may benefit from an artificial airway as a means of providing effective suction. Impaired mucociliary clearance occurs in patients exposed to high oxygen concentrations or other airway irritants (including particulate and gaseous components of smoke), those experiencing severe hypoxia or hypercarbia, and, paradoxically, those who have airway trauma induced by endotracheal intubation and suctioning. Endotracheal intubation also provides an effective means of delivering drugs during cardiopulmonary resuscitation when venous or intraosseous access is not available (see Chapter 42).

Physiologic Effects of Intubation

Laryngoscopy is a potent physiologic stimulus (Box 129.2).[28,29] At the very least, laryngoscopy is uncomfortable, causing significant pain and severe anxiety, especially in children who cannot understand or accept the need for it. Laryngoscopy causes an increase in systemic blood pressure and heart rate initiated by pressure on the back of the tongue or lifting the epiglottis.[28,30] This effect is augmented by endotracheal intubation and suction.[31] Nodal or ventricular dysrhythmias may occur. Sensory impulses triggering this reflex probably are carried along the vagus nerve supplying the base of the tongue, epiglottis, and trachea. The efferent limb is less well defined but most likely is the product of enhanced sympathetic activity. Infants respond more variably than do older patients. Hypertension develops in most patients, but a few become hypotensive, especially if they are hypoxic.[32] They may demonstrate moderate-to-severe bradycardia rather than tachycardia, perhaps as a consequence of their greater parasympathetic tone. Sedation and light anesthesia decrease but do not obliterate the hypertension and tachycardia; surface anesthesia and deeper general anesthesia

are more effective.[33] Children with previous hypertension display an exaggerated vasopressor response. Sedation and neuromuscular blockade during airway manipulation in infants minimize the associated bradycardia and systemic hypertension.[34-38] The impact of positive pressure ventilation on cardiac performance depends on the underlying disorder (discussed in Chapters 26 and 43) but should be carefully considered in preparation for intubation.

Box 129.2

Potential Physiologic Effects of Laryngoscopy and Intubation

Pain

Tachycardia

Anxiety

Bradycardia

Hypoxia

Systemic hypertension

Hypercarbia

Decreased systemic venous return

Increased intraocular

Decreased jugular venous pressure return

Increased intragastric pressure

Increased intracranial pressure

Laryngospasm

Bronchoconstriction

Pulmonary hypertension

Laryngoscopy and intubation are potent stimulators of laryngospasm and may cause bronchoconstriction, especially in patients with a history of reactive airway disease. Increased airway resistance probably results from parasympathetic stimulation, with release of acetylcholine and stimulation of muscarinic receptors on airway smooth muscle, especially large central airways.

During intubation, oxygen delivery to the patient is commonly interrupted. Ineffective breathing or apnea increases the likelihood of hypoxia, especially in children, with their relatively low functional residual volume and higher basal

metabolic rate. Patients with severe pulmonary disease and abnormally low functional reserve capacity are at particular risk.[34,37] During apnea, carbon dioxide tension increases at a rate of 3 to 4 mm Hg/min in healthy, sedated adults and probably more rapidly in children, particularly those with severe cardiopulmonary disease or increased metabolic rate resulting from fever, sepsis, or pain.[39,40]

ICP rises immediately during laryngoscopy even in patients without intracranial pathology before changes in blood gas tensions occur.[33,35,40-42] Cerebral metabolic rate and blood flow increase. Hypoxia, hypercarbia, and diminished jugular venous drainage, particularly in struggling patients, contribute further to increases in cerebral blood volume and increased intracranial pressure. Although normally transient, such intracranial hypertension may predispose patients with coagulopathies or vascular malformations to intracranial hemorrhage. Systemic hypertension in patients with impaired autoregulation of the cerebral circulation (eg, sick infants or patients with a variety of intracranial disorders) and impedance to jugular venous return by jugular compression, pneumothorax, or coughing and struggling stress both the arterial and venous sides of the cerebral circulation. In patients with poor intracranial compliance, this effect is exaggerated and prolonged. In infants without primary central nervous system disease, muscle paralysis (even without sedation or analgesia) effectively blocks the rise in ICP associated with intubation.[37] The systemic hypertensive response is generally unaffected by neuromuscular blocking agents but can be modified by analgesia and sedation or intravenous anesthesia.

Patients with severe pulmonary hypertension are at high risk for adverse effects of laryngoscopy. Decreased oxygenation and progressive hypercarbia lead to elevated pulmonary artery pressure. The noxious stimulus of visualizing the airway in itself may precipitate life-threatening hypertension.

Recognition of a Difficult Airway

Recognition of a difficult airway is important if potentially lethal surprises in airway management are to be minimized (Box 129.3). Although the intensivist is usually focused on the immediate physiologic disturbances affecting the patient, careful preparation and as thorough an evaluation of each individual patient as is possible is critical. Key components of the history and physical examination, as well as the clinical scenario, can provide insight into potential problem airways. A history of difficult intubations in the past or episodes of upper airway obstruction (including snoring or sleep apnea) suggest structural abnormalities that may or may not be evident at the moment. Recent tonsillectomy and adenoidectomy, cleft palate repair, or any prolonged surgical procedure resulting in oral edema or bleeding increase the likelihood of difficulty. Examining facial structure is essential, and inspecting the child's profile is particularly important because significant abnormalities may not be fully apparent on frontal view alone (Fig. 129.4). Certain genetic syndromes are associated with craniofacial anomalies, midline defects, or neuromuscular disorders that may make successful intubation via standard techniques exceptionally difficult.[43] Treacher Collins syndrome (mandibulofacial dysostosis), Goldenhar syndrome (oculoauriculovertebral dysplasia), Down syndrome, Pierre Robin syndrome, and the mucopolysaccharidoses, such as Hurler syndrome and Hunter syndrome, are a few of the syndromes that have characteristic features that suggest a

high probability of facing a challenging airway. Isolated micrognathia, macroglossia (glossoptosis), facial clefts, midface hypoplasia, prominent upper incisors or maxillary protrusion, facial asymmetry, a high arched narrow palate, a small mouth, and a short, muscular neck or morbid obesity are features that can interfere with effective bag-mask ventilation or visualization of the larynx. Limited temporomandibular joint or cervical spine mobility may make laryngoscopy and tube placement difficult. Midface instability or upper airway bleeding, edema, airway or neck masses and foreign bodies are additional reasons for concern.[44-49]

Box 129.3

Recognizing the Difficult Airway

Nasal obstruction

Limited neck mobility

FIG. 129.4 Importance of inspecting the patient's profile. Child with significant micrognathia, not immediately apparent on frontal view. (From Lipton JM, Ellis SR. Diamond-Blackfan anemia: diagnosis, treatment, and molecular pathogenesis. Hematol Oncol Clin North Am. 2009;23:261-282, 2009.)

Several classification systems assist with recognition and classification of the adult patient with a difficult airway. Although never validated in pediatrics, they provide a useful framework for assessing infants and children. The Mallampati classification (Fig. 129.5) assesses visualization of upper airway structures prior to intubation—particularly the uvula, soft palate, and faucial pillars—as a guide to the likely ease of intubation. Mallampati class 1 allows visualization of the uvula, soft palate, and faucial pillars; in class 2, faucial pillars and soft palate are visualized, but the base of the tongue obstructs the uvula; in class 3 only the soft palate is visualized; and in class 4 the soft palate is not seen. Difficult intubation is more likely associated with classes 3 and 4. This scale can be used with cooperative children, and an approximate evaluation may be obtained by observing many crying infants and young children.[50]

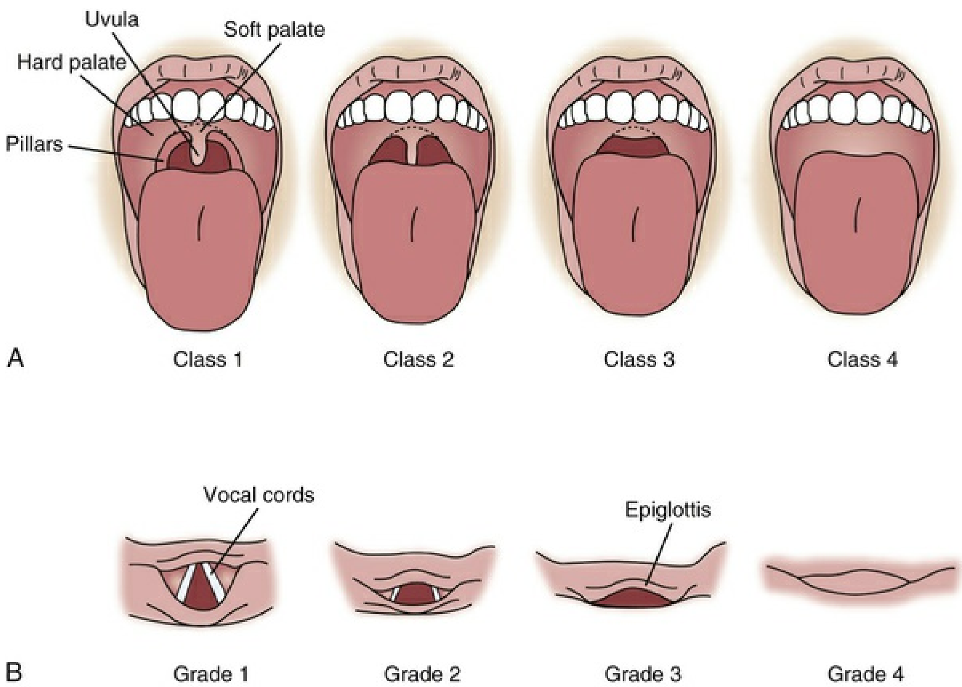

FIG. 129.5 (A) Modified Mallampati classification. Class 1: Visualization of the faucial pillars, uvula, soft and hard palate. Class 2: Visualization of complete uvula and palate. Class 3: Visualization of only the base of the uvula and palate. Class 4: Visualization of only the hard palate. (B) Cormack and Lehane classification of the laryngeal exposure. Grade 1: Most of the glottis is visible. Grade 2: Only the posterior portion of the glottis visible. Grade 3: Only the epiglottis is visible. Grade 4: Not even the epiglottis is visible. (From Amantéa SL, Piva JP, Zanella MI, et al. Rapid airway access. J Pediatr [Rio J]. 2003;79[suppl 2]:S127-138.)

The Cormack laryngeal view grade score is shown in Fig. 129.5B. Because the Cormack system requires an attempt to visualize the larynx, it is more valuable as a tool for describing difficulty once it has been encountered than for predicting it. The Cormack score is grade 1, full view of vocal cords and glottis; grade 2, partial view of vocal cords and glottis; grade 3, only the epiglottis is seen; and grade 4, the glottis and epiglottis are not visualized. Grades 3 and 4 predict difficult direct laryngoscopy. Although these classification systems are helpful in a controlled environment, particularly the preoperative area of a hospital, they are recognized as having limited utility in the emergent situations often encountered in the intensive care unit (ICU), and their ability to predict the degree of difficulty with intubation in children is not well established.

Ability to visualize the faucial pillars, soft palate, and uvula usually predicts an uncomplicated intubation, but this may be difficult to assess in a sick, uncooperative child.[42] Children with severe hypoxia, severe hypovolemia, or other causes of hemodynamic instability, such as intracranial hypertension, a full stomach, or a combination of these conditions, present added difficulties that must be considered.

When airway problems are anticipated, the intensivist should approach intubation with a plan specific to the difficulty noted and with a backup strategy in mind.[46-48] Extra equipment should be on hand, including a variety of laryngoscope blades, forceps, tubes, bronchoscopes, tracheostomy or cricothyrotomy trays, and additional skilled personnel as needed.[48] Many institutions have developed difficult airway

carts or packs, as well as a team of highly skilled airway experts, to assist when severe intubation challenges arise.[50-51] If sedation is required, agents that can be reversed pharmacologically are desirable and should be titrated slowly to the desired effect. Fig. 129.6 shows a modification of the American Society of Anesthesiologist's difficult airway algorithm and provides an approach to managing the difficult airway.[52] A similar plan is necessary at the time of extubation, with serious consideration given to extubation in the operating room or with an airway exchange catheter left in place to facilitate reintubation if necessary.

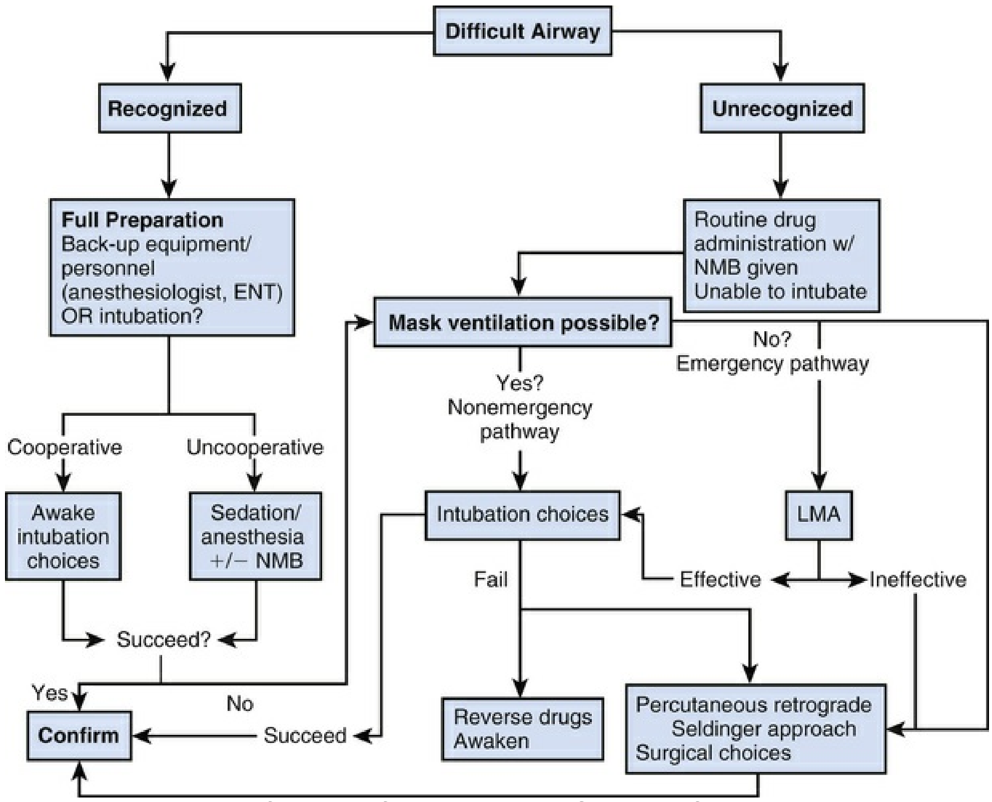

FIG. 129.6 Modification of the American Society of Anesthesiologist's difficult airway algorithm. (From Practice guidelines for the management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Anesthesiology. 2003;98:1269.)

Process of Intubation

All equipment for intubation must be available prior to the procedure (Fig. 129.7). A source of suction and appropriate catheters, oxygen and necessary tubing, ventilation bag, mask, laryngoscope and proper-sized blade with a well-functioning light, endotracheal tubes of the expected size and larger and smaller sizes, airway forceps, stylet, and a means of securing the endotracheal tube should be present at the head of the bed so that the intubator does not need to look away from the patient. A functioning intravenous catheter for drug infusion is essential in all but the most extreme emergencies.

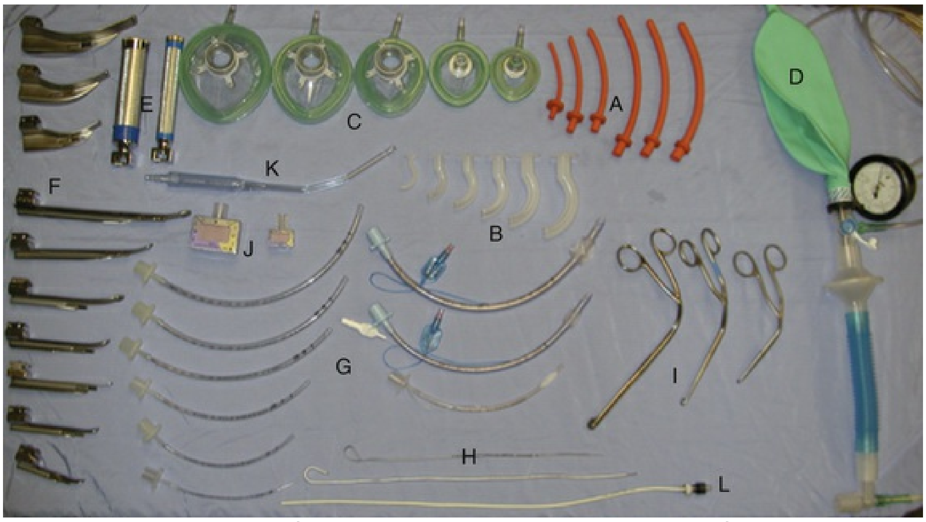

FIG. 129.7 Equipment for intubation, showing a variety of sizes available for pediatric patients. (A) Nasopharyngeal airways. (B) Oral airways. (C) Masks. (D) Anesthesia (Mapleson) bag. (E) Laryngoscope handles. (F) MacIntosh (curved) and Miller (straight) laryngoscope blades. (G) Uncuffed and cuffed endotracheal tubes. (H) Endotracheal tube stylets. (I) Magill forceps. (J) End-tidal CO_2 detectors. (K) Yankauer suction. (L) Tube changer.

Laryngoscope handles are available in standard adult and pediatric sizes. The smaller diameter of the pediatric handle makes it easier to manipulate, particularly when intubating infants and very young children. Blades of many descriptions are available. The most important characteristic is length. Inexperienced operators often select a blade that is too short, making visualization of the larynx difficult. Excessively long blades make it difficult to avoid pressure on the upper lip and teeth. Historically straight blades have been recommended for intubating infants and young children, but recent evidence suggests curved blades (eg, Macintosh 1 or 2 blades) are as likely to provide good visualization.[53] The slightly curved tip of the Miller blade makes visualization of the larynx possible without actually lifting the epiglottis. The broader blade and bore of the Wis-Hipple blade helps displace soft tissues in the young infant's oropharynx. The Miller no. 2 blade is especially versatile in a broad age group (ie, children about 3 to 10 years of age). In older children, use of a curved blade often works best. If a cuffed endotracheal tube is to be used, a curved Macintosh no. 2 or 3 blade is effective in the majority of patients and may provide more room to manipulate a cuff in the oropharynx. Operator experience is probably most important, with willingness to try the alternative blade if one provides a poor view of the airway.

Selecting the proper tube size (diameter) is important, both to achieve effective mechanical ventilation and to prevent tracheal injury. A variety of formulas are in use, with the most common being that of Cole: Tube size (inner diameter) = (Age [years]/4) + 4. Cuffed tubes typically should be a half size smaller. For infants, no formula is accurate. Table 129.2 gives reasonable guidelines. Individual differences require that the tube size be modified for each child so that the tube passes easily, but it fits snugly enough to allow delivery of adequate mechanical breaths at a given chest compliance.

TABLE 129.2

Guidelines for Endotracheal Tube Diameter in Infants and Children

Age	Internal Diameter	Orotracheal Length (cm)	Nasotracheal Length (cm)
Premature	2-3	6-8	7-9
Newborn	3-3.5	9-10	10-11
3-9 mo	3.5-4	11-12	11-13
9-18 mo	4-4.5	12-13	14-15
1.5-3 y	4.5-5	12-4	16-17
4-5 y	5-5.5	14-16	18-19
6-7 y	5.5-6	16-18	19-20
8-10 y	6-6.5[a]	17-19	21-23
11-13 y	6-7[a]	18-21	22-25
14-16 y	7-7.5[a]	20-22	24-25

[a]Cuffed tube.

Ideal tube size varies according to age, height, weight, specific airway anatomy, and ventilatory requirements of a child. In general, an air leak around the tube at 15 to 30 cm H_2O pressure is desirable.

Based on traditional teaching about the anatomy of the airway, cuffed endotracheal tubes were viewed as not necessary or appropriate in young pediatric patients (younger than 8 years). However, better recognition of the elliptical shape of the young child's airway shows that a tube that permits a small leak around the tube (as previously recommended) may still be compressing the lateral aspects of the tracheal mucosa (Fig. 129.1D). Cuffed tubes allow better occlusion of the airway with potentially lower pressure on the mucosa, with potentially better oxygenation and ventilation, more reliable end-tidal CO_2 monitoring, and decreased risk of aspiration. They are increasingly being used for patients of all ages. Cuffed tubes have routinely been recommended for children older than 8 years. In addition, the greater elastic recoil of the lungs and chest wall of older patients may demand higher airway pressures for effective ventilation.

Cuffed tubes of all sizes are available and are especially useful in patients in whom consistent minute ventilation is essential (eg, in the presence of severely elevated ICP or reactive pulmonary vasculature) or those requiring relatively high airway pressures. Increasing evidence indicates that cuffed tubes can be used in young children without higher incidence of airway complications.[54-59] It appears that tubes with clear depth markers along their length and an ultrathin, polyurethane, high-volume, low-pressure, spherical rather than elliptical cuff, positioned close enough to the tip of the tube to avoid inflation in the larynx are ideal.[6] When a cuffed tube is used, great care should be taken to inflate it with the *minimum occlusive volume,* the minimum volume required to just seal the gas leak around the tube during mechanical inspiration and prevent mucosal ischemia and subsequent tracheal damage. Our current best understanding is that pressure within the cuff should be maintained below 20 to 30 cm H_2O. There are inexpensive devices for measuring cuff pressure built into syringes used to fill the cuff. In addition, a standard pressure transducer with air-filled tubing can be attached to the pilot balloon on the endotracheal tube and attached to a typical ICU monitor for continuous pressure measurements. Potential advantages of cuffed tubes include decreased likelihood of multiple intubations to identify the correct size and avoidance of changing the endotracheal tube of a critically unstable patient if lung disease worsens. In addition, absence of a significant leak around the endotracheal tube (ETT) may decrease the likelihood of flow-triggered ventilator autocycling. The ability to occlude the leak also facilitates pulmonary function testing and indirect

calorimetry.

Pharmacologic Agents Facilitating Intubation

Although intubation often is possible without use of drugs, the physiologic and psychologic benefits of their use usually outweigh the disadvantages.[60,61] An analysis of data in the pediatric National Emergency Airway Registry shows that the intubation success rate is higher when both sedation and neuromuscular blockade are used.[62] This finding is equally true in neonates, in whom sedation and neuromuscular blockade are still commonly not used, with no evidence they are harmful.[63] In neonates the predominance of evidence indicates that use of neuromuscular blockade is associated with a lower risk of intracranial hemorrhage and pulmonary airleak.[64] Excellent technical airway skills are an absolute prerequisite, however, because loss of control of the airway invites catastrophe. Drugs facilitating intubation are listed in Table 129.3.

TABLE 129.3

Drugs Facilitating Intubation

Drugs	Dose	Duration	Comments
Intravenous Anesthetics			
Etomidate	0.3 mg/kg IV	3-5 min	Anesthesia, adrenal suppression (↑ mortality in sepsis?), minimal CV effect, apnea, ↓ $CMRO_2$, ↓ CBF, ↓ ICP
Ketamine[a]	1–2 mg/kg IV; 4–6 mg/kg IM	10-15 min	Anesthesia, ↑ systemic arterial pressure, ↑ HR, ↑ ICP, ↑ IOP, hallucinations, laryngospasm, bronchodilation
Propofol	1–3.5 mg/kg IV, then 0.05–0.3 mg/kg/min	10-15 min	↓ Systemic arterial pressure, ↓ $CMRO_2$, ↓ CBF, ↓ ICP, metabolic acidosis
Sedatives/Analgesics			
Fentanyl[a]	2–5 μg/kg IV	30-90 min	Analgesia, respiratory depression, cardiovascular stability, occasional bradycardia, or chest wall rigidity
Remifentanil	1–3 μg/kg, then 0.25–1 μg/kg/min		Analgesia, respiratory depression, cardiovascular stability
Morphine[a]	0.1–0.2 mg/kg IV	2-4 h	Analgesia, respiratory depression, ↓ systemic arterial and venous tone, ↓ systemic blood pressure
Midazolam[a]	0.1–0.3 mg/kg IV	1-2 h	Amnesia, sedation or euphoria, ± cardiovascular stability, occasional respiratory depression
Lorazepam	0.1–0.3 mg/kg IV	2-4 h	Sedation, anxiolysis, minimal cardiovascular effect
Neuromuscular Blocking Agents			
Rocuronium[a]	0.6–1.2 mg/kg IV	15-45 min	Minimal cardiovascular effect, prolonged duration in liver failure
Vecuronium[a]	0.1–0.3 mg/kg IV	30-75 min	Minimal cardiovascular effect, prolonged effect in hepatic failure
Cis-atracurium	0.1 mg/kg, then 1–5 mg/kg/min	20-35 min	Metabolized by plasma hydrolysis, mild histamine release
Atracurium	0.5 mg/kg	30-40 min	Metabolized by plasma hydrolysis, mild histamine release
Succinylcholine[a]	1–4 mg/kg IV	5-10 min	↓ HR, K^+ release in neuromuscular disease, trauma or burns, masseter spasm, malignant hyperthermia, myoglobinuria

[a]Agents may be given intramuscularly but will have slower onset and more variable duration of effect.

Duration of effect is only approximate and varies with age and physiologic state of the patient.

CBF, cerebral blood flow; *$CMRO_2$*, cerebral metabolic oxygen requirement; *CV*, cardiovascular; *HR*, heart rate; *ICP*, intracranial pressure; *IM*, intramuscular; *IOP*, intraocular pressure; *IV*, intravenous.

Anticholinergic Agents

Anticholinergic agents decrease oral secretions and prevent bradycardia, particularly in young infants, although their use is not universally recommended.[65,66] Atropine

(0.02 mg/kg) and glycopyrrolate (0.01 mg/kg intravenously) are both effective. Scopolamine provides amnesia, decreases secretions, and prevents bradycardia. The drying effect commonly requires approximately 15 to 30 minutes and is rarely achieved in emergency intubation. Pediatric Advanced Life Support (PALS) guidelines (2011) recommend atropine for rapid sequence intubation for infants under age 1 year, patients 1 to 5 years of age receiving succinylcholine, patients older than 5 years receiving a second dose of succinylcholine, and patients with bradycardia present before intubation; these guidelines are silent regarding patients older that 1 year, not receiving succinylcholine.[67]

Sedative and Analgesic Agents

Most patients benefit from some degree of sedation. Drugs commonly used include intravenous anesthetic agents, anxiolytic agents, and narcotic analgesics. The appropriate choice in a particular patient depends on the child's hemodynamic status, level of anxiety, and underlying disease process.

Etomidate is a short-acting intravenous anesthetic that causes rapid loss of consciousness (at 0.3 mg/kg) and respiratory depression. It also decreases cerebral oxygen consumption, cerebral blood flow (CBF), and ICP, without significant detrimental effects on cardiovascular function and with less respiratory depression than thiopental, an agent widely used in the past but no longer readily available in the United States. These characteristics have led to its common use for emergency intubation.[68,69] It has no analgesic properties and may be best combined with a narcotic analgesic. Adverse effects include vomiting, myoclonus, and lowering of the seizure threshold. With continuous infusion for sedation, it can cause adrenal insufficiency, making it inappropriate for long-term use in the ICU.[70] Growing evidence suggests it may suppress adrenal function even after a single dose, particularly in patients with sepsis and shock, raising questions about its use in these settings.[71-83]

Ketamine is another potent non-narcotic analgesic and anesthetic that has been used safely in children in the critical care setting.[84,85] It increases heart rate, systemic blood pressure, and cardiac output and is a fairly potent bronchodilator. However, myocardial depression may be apparent after administration to patients with catecholamine depletion. Its use in patients with unstable hemodynamics did not seem to be associated with a lower prevalence of new hypotension noted in a multicenter prospective observational cohort study.[86] It may be of particular value in patients with status asthmaticus or other reasons for bronchospasm and may have a beneficial effect in sepsis. Spontaneous ventilation is preserved in most patients, but laryngospasm may occur.[87] Although in the past it has been considered inappropriate for patients with intracranial hypertension because of evidence that it increases cerebral metabolic rate, blood flow, and ICP, more recent studies indicate that it may be used safely in these patients, although no clear consensus has emerged.[88-90] Emergence delirium and hallucinations occur frequently and may be prolonged and recurrent, particularly in adolescents and young adults. Use of ketamine for a variety of procedures in children has been successful, with little reported difficulty with neuropsychiatric complications, but follow-up in most studies has been short and superficial.[91-96] Whereas the majority of patients do not suffer severe disturbances, those who do may have severe and prolonged distress. Benzodiazepines or barbiturates may decrease the incidence and severity of such

adverse effects and the incidence of vomiting, although the data in children are limited and conflicting.[75,81,91,93,97,98]

Propofol is an ultra–short-acting agent with rapid onset and offset unless given by continuous infusion. It causes respiratory depression, desaturation, and systemic hypotension secondary to its negative inotropic effects and peripheral venous and arterial vasodilation. Its role in airway management of critically ill children is limited because of these effects. It has gained widespread acceptance as an anesthetic agent in children, however, and has been used extensively for procedural sedation.[99,100] Use in the ICU for more than approximately 6 hours is not recommended because of its still unexplained association with metabolic acidosis, cardiovascular collapse and death, and propofol syndrome among pediatric ICU patients.[100-103] Current labeling warns against its use for prolonged sedation in children.

The benzodiazepines, including diazepam and midazolam, relieve anxiety, produce sedation in most children, and provide amnesia for noxious procedures. They do not relieve pain. They have relatively little hemodynamic effect in most patients and rarely interfere with spontaneous breathing at therapeutic doses. They decrease cerebral oxygen consumption modestly. They are best combined with a narcotic analgesic when used for intubation in order to decrease the discomfort and pain associated with laryngoscopy and passage of the tube.

Narcotics commonly used for intensive care include morphine, fentanyl, and some of the ultra–short-acting agents such as remifentanil. They cause respiratory depression in a dose-dependent fashion and increase intracranial blood flow in proportion to the increase in $PaCO_2$. If hypercarbia is prevented, they decrease cerebral metabolic rate and blood flow. In the setting of altered cerebral autoregulation, they may not protect the patient from alterations of CBF.[104,105] Morphine causes histamine release and peripheral vasodilation and may precipitate systemic hypotension. Fentanyl is approximately 100 times more potent than morphine but does not release histamine and has little hemodynamic effect, even at anesthetic doses. Large doses given rapidly can cause bradycardia or chest wall rigidity. Remifentanil is a rapid-onset, ultra–short-acting opiate that is even more potent than fentanyl and may have potential benefit in intubation for procedures.

Neuromuscular Blocking Agents

Neuromuscular blocking agents cause reversible paralysis, facilitating visualization of the airway and insertion of the endotracheal tube in an atraumatic fashion. Most drugs in use are nondepolarizing relaxants with similar action. Differences are primarily in their hemodynamic effects, metabolism, and excretion.[106,107] Vecuronium and rocuronium are the agents most commonly used. Both are amino-steroid agents. Vecuronium has virtually no hemodynamic effect. Its duration of action varies depending on the patient's age, approximately 70 minutes in infants and 35 minutes in older children. It is metabolized exclusively by the liver. Rocuronium provides good intubating conditions nearly as rapidly as succinylcholine (in about 45 to 90 seconds)[108-110] without the adverse effects. Its duration is longer at 15 to 45 minutes (and longer in infants).[111-113] Like vecuronium, it has minimal hemodynamic effect, is metabolized by the liver, and largely is excreted in bile (with a small amount excreted by the kidneys). Atracurium and cis-atracurium, both benzylquinolinium agents, also have minimal hemodynamic effects in most patients but may cause

histamine release and hypotension in some persons. Metabolism occurs by spontaneous plasma hydrolysis; thus neither renal nor hepatic function is necessary for elimination. Duration of action is short at about 15 to 20 minutes.

The only depolarizing relaxant in clinical use is succinylcholine. Its only advantage is its rapid onset of action (45 to 60 seconds) and brief duration of action (5 to 10 minutes). Muscle fasciculations occur at the onset of action in patients older than 4 years and may increase intracranial, intraocular, and intragastric pressure. Defasciculating doses of a nondepolarizing neuromuscular blocker prior to succinylcholine administration minimize such effects. Massive hyperkalemia may occur following its use in patients with spinal cord injury, severe burns, crush injuries, or neuromuscular disease. More recently, the spread of acetylcholine receptors outside of the neuromuscular junction, the mechanism presumed to underlie the massive hyperkalemic response previously noted, has been recognized to occur in many forms of critical illness associated with immobility, placing many critically ill patients at risk.[114] It is a known trigger for malignant hyperthermia, even in the absence of volatile anesthetic exposure, and is a particular risk to patients with previously undiagnosed myopathies, often associated with abnormality in the ryanodine receptor type one gene (*RYR1*).[115] It frequently causes myoglobinuria in otherwise healthy children. The US Food and Drug Administration has issued a warning against its use for routine intubation in children because of these complications. Although it is frequently used for emergency intubations and is widely recommended,[62,116,117] the difference in time to conditions for intubation between succinylcholine and rocuronium is small (~30 seconds), rarely of clinical significance, and inadequate to justify the added risk in the majority of cases. Moreover, the time to critical hemoglobin desaturation in the case of a failed airway is shorter than its duration of action, especially in children, so its shorter duration of action does not provide a meaningful advantage over nondepolarizing blockers.[118]

A more extensive discussion of anesthetic agents and their use is given in Chapters 130, 131, 133, and 134.

Orotracheal Intubation

When all equipment is ready, an assistant is assigned to monitor the child's color, heart rate, blood pressure, and oxygen saturation and to administer drugs when ordered. The child is placed supine with the head in the "sniffing" position. The infant's large occipitofrontal diameter naturally results in good position most of the time, but a small pad under the shoulders may be helpful. In older children, a thin pad under the occiput helps establish slight neck flexion (Fig. 129.8). The head is extended to align the oral, pharyngeal, and laryngeal axes as much as possible. Spontaneous or manual ventilation with supplemental oxygen is maintained as drugs to facilitate intubation are given. Many patients requiring emergency intubation have severely impaired gas exchange and may require several minutes of breathing 100% oxygen, often with positive inspiratory and end expiratory pressure.[119] Applying cricoid pressure during manual ventilation helps minimize gastric distention by air (Fig. 129.9).[120] After the drugs take effect, the pharynx is suctioned and stomach contents are aspirated. The patient is again briefly oxygenated, and the mask is removed. In a fully relaxed patient in good position, the mouth falls open. It can be opened more widely with caudad pressure on the chin by

the intubator's left fifth finger as the laryngoscope is introduced into the right-hand corner of the mouth. In an unsedated patient or when the mouth opens abnormally, it may be necessary to open the jaw with the often recommended scissor-like use of the right thumb and forefinger, but this action places the intubator at risk of both trauma and infection and should be avoided when possible.

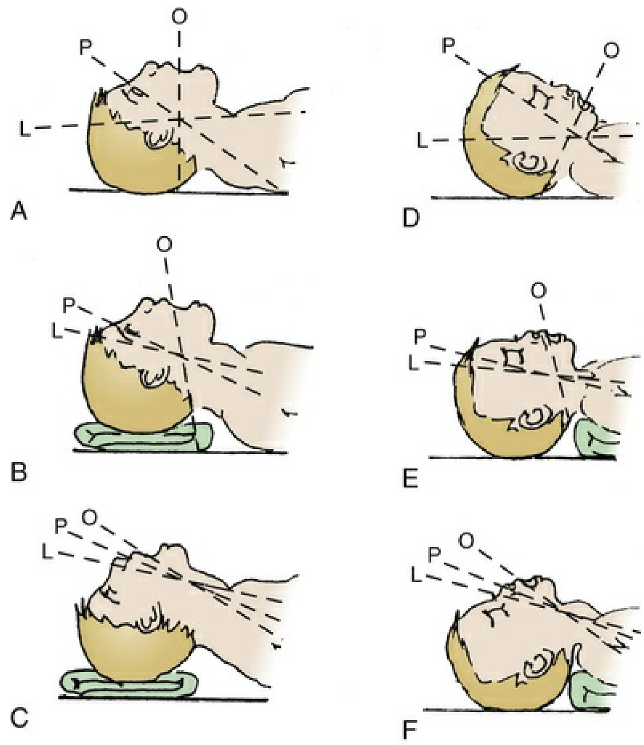

FIG. 129.8 (A) Positioning of the young child and infant for laryngoscopy and tracheal intubation. (B) Placing the child's head on a thin pad flexes the neck slightly and helps align the pharyngeal and laryngeal axes. (C) Extension of the atlantooccipital joint (into the sniffing position) further aligns the oral axis with the pharyngeal and laryngeal axes. (D) Before the age of approximately 3 years, the child's large frontal occipital diameter makes the pad beneath the head unnecessary, but a small pad under the shoulders (E) may improve alignment of the pharyngeal and laryngeal axes. (F) As with the older child, head extension improves alignment of the oral, pharyngeal, and laryngeal axes. (From McAllister JD, Gnauck KA. Rapid sequence intubation of the pediatric patient: fundamentals of practice. Emerg Med. 1999;46:1249-1284.)

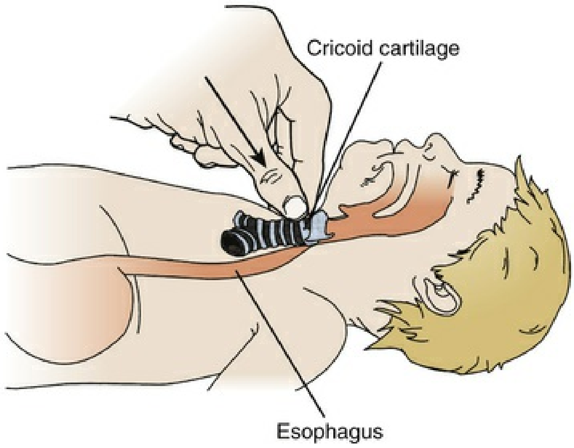

FIG. 129.9 Sellick maneuver. Pressure on the cricoid cartilage occludes the esophagus or hypopharynx.

The laryngoscope is gently advanced into the pharynx and leftward, sweeping the tongue out of the way. Holding the handle at a 45-degree angle to the bed and lifting along the line of the handle to avoid pressure on the lips, teeth, or alveolar ridge, the intubator displaces the mandible until the vocal cords are in view (Fig. 129.10). Application of gentle cricoid pressure by an assistant may be helpful. Once the larynx is clearly visualized, the tube is advanced from the right corner of the mouth into the larynx (not through or along the blade itself). An appropriate sized tube usually passes easily. The nearly universal tendency to plumb the depths of the child's airway with extra centimeters of tube results in main stem intubation. Unfortunately, the recommendation to use three times the ETT size for appropriate depth of tube placement for a child results in malposition in 15% to 25% of patients.[121] Placement is likely to be better if the intubator is careful to place the appropriate markings near the tip of the endotracheal tube at the level of the cords. If such markings are absent, careful attention to advancing the tip of the tube only a few centimeters (2 to 4 cm) beyond the cords prevents main stem intubation.

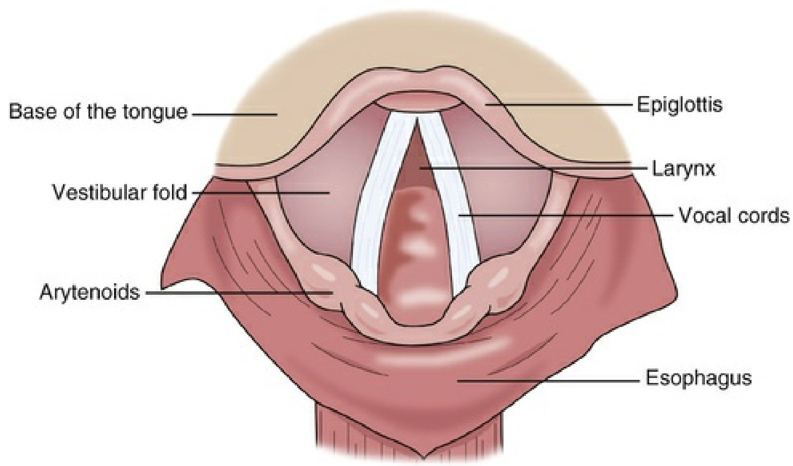

FIG. 129.10 Glottic area view via laryngoscopy.

With the tube in place, the child again receives manual ventilation with oxygen. Typically a small air leak around the tube is present. Assuming use of a cuffed tube,

the cuff is inflated to less than 20 to 30 cm H_2O or lowest pressure that occludes the leak. Correct tracheal placement of the tube is suggested by observation of moisture condensing in the tube, good chest excursion, symmetrical breath sounds, and effective oxygenation. The most reliable means of ensuring proper placement, following clear visualization of the tube passing between the vocal cords, is documentation of carbon dioxide in expired gas (by capnometry or a disposable CO_2 detector). Only in the settings of full cardiac arrest or extremely low pulmonary blood flow can the endotracheal tube be in the airway without detection of expired carbon dioxide. Under other conditions, malposition of the tube, most commonly in the esophagus, must be assumed. It is important to remember that capnometry does not ensure correct positioning within the airway: Carbon dioxide will be detected with the tube anywhere from a bronchus to above the vocal cords. Documenting location of the tip of the tube between the thoracic inlet and T4 on chest radiograph, with the head in a neutral position, is important. The tip will descend deeper into the trachea with neck flexion and move cephalad with neck extension.[122,123] With the endotracheal tube in good position, an inflated cuff often can be palpated at the sternal notch when quick pressure is applied to the sentinel balloon. The tube is secured, avoiding pressure on the lips, particularly at the angle of the mouth, and keeping the vermilion border of the lip free of tape.

Nasotracheal Intubation

If nasotracheal intubation is preferred, it should generally follow orotracheal intubation so that an assistant can ventilate the child while the somewhat more difficult intubation is accomplished. A topical vasoconstricting agent such as phenylephrine 0.25% or oxymetazoline 0.05%, sprayed into the nasal fossa, minimizes the risk of bleeding. In most children a tube of the same diameter as the oral tube can be gently advanced along the floor of the nasal cavity, essentially directly posteriorly, into the nasopharynx with firm, but not brutal, pressure. With the oral tube in the left corner of the mouth, the laryngoscope is again advanced into the pharynx until the oral tube is visualized passing through the cords and the tip of the nasal tube is seen in the nasopharynx. The nasal tube is advanced until it lies directly above the cords, anterior to the oral tube. Use of Magill forceps may facilitate this maneuver. When the nasal tube is in good position to enter the larynx, the assistant removes the oral tube and helps advance the nasal tube. Difficulty advancing the tube after it has passed the vocal cords may be overcome by rotating the tube or flexing the neck. The tube then is secured; pressure on the septum or anterior rim of the nares should be avoided.

Although an orotracheal tube usually is placed more rapidly in emergencies, it often stimulates gagging, makes mouth care difficult, and it is more easily kinked or bitten. Anchoring the tube often is difficult because of saliva, and tongue movement may contribute to palatal or tracheal erosion and increase the likelihood of accidental extubation. Trauma to lips, teeth, tongue, and other oropharyngeal structures may occur. Nasotracheal intubation is more comfortable for most conscious patients, causes less stimulation of the gag reflex, is more easily secured, and prevents the problem of biting in patients with seizures, decerebrate rigidity, or extreme agitation. However, bleeding, adenoid injury, sinusitis, and trauma to the nasal turbinates, septum, or nares may occur with nasotracheal intubation, and the risk of

sinusitis is greater than with orotracheal tubes.[124,125] Contraindications to nasotracheal intubation include coagulopathy, maxillofacial trauma, CSF leak, and basilar skull fracture.

Video Laryngoscopy

Video laryngoscopy allows visualization of the larynx without requiring a direct line of sight aligning the oral, pharyngeal, and tracheal axes. In the setting of a difficult airway, video assistance improves visualization and more rapid intubation in adults. Visualization in children is also improved, but experience published to date suggests that the first-pass success rate is lower and time to intubation is longer than with direct laryngoscopy, even in the hands of experienced anesthesiologists, at least in patients in whom airway visualization is only moderately difficult.[126-130] On the other hand, studies of simulated difficult airway management in infants have shown improved intubation rates without a longer time to intubation.[128] At present, it appears that these devices may be most valuable in difficult situations, including cervical spine instability and craniofacial abnormalities, rather than as an advance in routine laryngoscopy.[131]

The video laryngoscope also provides a useful opportunity for teaching airway skills. Some devices include laryngoscope blades similar to standard Mac and Miller blades. A duplicate video image allows an instructor to view the attempted routine intubation in real time and provide immediate guidance and evaluation.[132,205]

Flexible Fiberoptic Bronchoscopy

Flexible fiberoptic bronchoscopy is an effective means of securing a difficult airway, especially in patients with cervical spine instability or those in whom limited jaw mobility or oropharyngeal lesions prevent good visualization of the larynx.[48,133] Assuming the operator's clinical proficiency, the procedure almost always is successful, with little or no trauma to the patient. The nasal route is routinely chosen because it is easier to use, better tolerated, and safer for the instrument than other routes. A topical vasoconstrictive agent and local anesthetic are applied to the nasal mucosa. The endotracheal tube is advanced through the nose into the nasopharynx, and the flexible scope is threaded through it. The scope is advanced through the vocal cords, and the tube is passed over it into the trachea. (Alternatively, the tube with its connector removed may be threaded retrograde over the scope. The scope is advanced through the nose, to the nasopharynx, and through the larynx into the trachea. The endotracheal tube is advanced over the bronchoscope into good position.) The bronchoscopist then visualizes and secures the position of the tube in the trachea and carefully withdraws the scope.

The flexible fiberoptic bronchoscope can also be used with an intubating laryngeal mask airway (LMA). Although the LMA is not used commonly in the PICU (except occasionally for procedural support), it can provide a means of securing a difficult airway. Once adequate oxygenation and ventilation are established, a fiberoptic scope can be threaded into the airway and an endotracheal tube advanced over it.[134,135]

Extubation

Extubation is appropriate when the conditions for intubation are no longer present. In general, this means that the work of breathing has decreased to a level manageable by the patient. In most cases, this situation occurs when oxygenation is adequate with the administration of 40% oxygen or less; spontaneous tidal volume is greater than 3.5 mL/kg; the patient can sustain a normal $PaCO_2$ without mechanical breaths with a near normal respiratory rate for age and without the use of accessory muscles; secretions are manageable; upper airway reflexes are intact; and neuromuscular function is sufficiently good to achieve an adequate vital capacity and maximum inspiratory pressure (Table 129.4).[136] Although standard teaching holds that extubation is most likely to be successful when there is an air leak around the ETT at less than 30 cm H_2O, study indicates that the presence or absence of a leak is a poor predictor of the success of extubation.[137] If intubation was for relief of upper airway obstruction, direct inspection revealing more normal anatomy is of particular value, and the significance of a leak may be greater. In patients with a previously difficult to manage airway, extubation over a tube changer or in the operating room, with surgical support available, should be considered.[138]

TABLE 129.4

Threshold Values for Low (≤10%) and High (≥25%) Risk of Extubation Failure

Variable	Low-Risk Value (≤10%)	High-Risk Value (≥25%)
V_{tspont} (mL/kg)	≥6.5	≤3.5
FiO_2	≤0.30	>0.40
Paw (cm H_2O)	<5	>8.5
OI	≤1.4	>4.5
FrVe (%)	≤20	≥30
PIP (cm H_2O)	≤25	≥30
C_{dyn} (mL/kg/cm H_2O)	≥0.9	<0.4
V_t/T_i (mL/kg/sec)	≥14	≤8

C_{dyn}, dynamic compliance; FiO_2, fraction of inspired oxygen; *FrVe*, fraction of total minute ventilation provided by the ventilator; *OI*, oxygenation index; *PIP*, peak ventilatory inspiratory pressure; V_{tspont}, spontaneous tidal volume indexed to body weight; V_t/T_i, mean inspiratory flow.

From Venkataraman ST, Khan N, Brown A. Validation of predictors of extubation success and failure in mechanically ventilated infants and children. Crit Care Med. 2000;282:991.

Before extubation, the child is given nothing enterally for 4 to 6 hours. The tube and pharynx are suctioned thoroughly, and the child is ventilated with 100% oxygen to provide a reservoir of oxygen as a buffer against laryngospasm at extubation. With the lungs fully inflated, the endotracheal tube is removed, and the child is provided with humidified oxygen and observed closely.

Postextubation stridor is common and may range from mild to life threatening. Children younger than 4 years are most frequently affected by postextubation stridor. Factors contributing to airway edema include a tight endotracheal tube or cuff, traumatic or repeated intubations, excessive movement of the tube (or patient), preexistent airway abnormalities, and airway infection.[139] Cool mist or humidified oxygen is sufficient treatment for children with mild symptoms. Nebulized racemic epinephrine (0.5 mL of a 2.25% solution in 2.5 mL of saline solution delivered intermittently or continuously) effectively relieves more severe upper airway obstruction in most children, probably by local vasoconstriction. Only the l-isomer in the racemic formulation is biologically active. Epinephrine available for

cardiovascular use is as safe, effective, and less expensive if half the racemic dose is used. Following its use, edema may recur, so close observation must continue. The value of corticosteroids is more controversial, in part because most studies do not differentiate multiple causes of croup.[140-148] Patients at high risk for postextubation stridor (eg, those with multiple intubation attempts) appear most likely to benefit.[143-145] Dexamethasone (0.3 to 0.5 mg/kg every 6 hours for 1 or 2 days) is recommended in selected cases.

The work of breathing through a narrowed upper airway can be decreased by inhalation of a low-density gas mixture. Oxygen in helium is less dense than air or pure oxygen and permits higher inspiratory flow at lower resistance. Helium-oxygen mixtures are commercially available, usually providing 20% oxygen in 80% helium. More oxygen can be added to the mix as needed. Although traditional teaching holds that at least 70% helium is necessary to decrease airway resistance enough to make a clinical difference in the work of breathing, experience demonstrates value at considerably lower concentrations.

If pharmacologic treatment is ineffective, noninvasive ventilatory support may prevent the need for reintubation, but meticulous attention to the patient's work of breathing is critical to recognize potential catastrophic airway obstruction. Reintubation with a smaller tube for 12 to 24 hours may be necessary, and continued dexamethasone treatment and sedation to minimize agitation and further trauma to the airway may permit resolution of symptoms. Persistent symptoms are an indication for diagnostic laryngotracheobronchoscopy.

Complications of Endotracheal Intubation

Complications of intubation can be divided into those related to placement of the artificial airway, those that occur while the endotracheal tube is in place, and those related to extubation or appearing late (Table 129.5). Immediate complications usually are related to the underlying disease process, the physiologic effects of laryngoscopy and intubation and administration of positive pressure, or direct trauma to airway structures. The child's general condition, tube size, cuff pressure, movement, airway infection, systemic perfusion, duration of intubation, and attention to meticulous airway care are factors influencing the development of problems during maintenance of the airway.[149] Laryngospasm, aspiration, and failure (or inability) to deflate a cuff cause complications at extubation. Although laryngeal or tracheal injury may be obvious at the time of intubation, symptoms may be delayed 2 to 6 weeks.

TABLE 129.5

Complications of Endotracheal Intubation

Immediate	Maintenance	Extubation/Late
Physiologic		
Hemodynamic instability	Obstruction	Laryngospasm
Dysrhythmias	Sinusitis	Gagging, vomiting
Apnea	Otitis (similar to immediate)	Aspiration
↓ PAO_2		Sore throat
↑ $PaCO_2$		Dysphonia, aphonia
Coughing		
Laryngospasm		
Gagging, vomiting, regurgitation,		

aspiration		
↑ Intracranial pressure		
↑ Intraocular pressure		
Traumatic		
Nasal septum laceration, perforation	Lip, tongue ulceration	Laryngeal or tracheal granuloma
Nasal turbinate injury	Nares ulceration	Vocal cord paralysis
Tooth loss or injury	Palatal erosion, cleft formation	Subglottic stenosis
Lip, tongue, palate laceration, hematoma	Vocal cord edema, ulceration	
Tonsillar or adenoid avulsion, laceration, hematoma	Laryngeal and tracheal mucosal ischemia, ulceration, necrosis	
Laryngeal strictures	Recurrent laryngeal nerve damage	
Cervical spine subluxation	Subglottic edema, ulceration	
Malposition		
Esophageal	Main stem intubation	
Main stem bronchus	Inadvertent extubation	
Intracranial	Atelectasis	
Soft tissue		

Prolonged Intubation

The safe duration of endotracheal intubation in infants and children is not clear. Since the 1950s, the accepted period has increased from less than 12 hours to an undefined much longer period. Subglottic stenosis is reported to occur in 1% to 8% of infants after prolonged intubation, but a similar incidence has been noted after intubation for less than 1 week.[150] In older infants, children, and adults, it is becoming clear that there is no clear safe period. Complications can occur immediately at intubation or may not be seen after many weeks or even months with an endotracheal tube in place.[151] The decision to switch to tracheostomy should not be based on an arbitrary time limit but rather on the relative advantages and disadvantages of one artificial airway over another in each individual patient.

Special Circumstances

Full Stomach

Patients with a full stomach are at high risk for aspiration of gastric contents during airway manipulation, particularly if protective airway reflexes are impaired. Much of the morbidity associated with aspiration can be attributed to the effects of acid aspiration. Aspiration of fluid with a pH below 1.8 is associated with a high incidence of severe pulmonary dysfunction and death. Aspiration of fluid with a pH between 1.8 and 2.5 produces symptoms of moderate severity. When fluid with a pH above 2.5 is aspirated, sequelae are less a consequence of the acid than of other characteristics of the material aspirated.[152] Other risk factors include the volume aspirated, the presence and nature of particulate food particles, contamination by bacterial pathogens, underlying pulmonary or systemic disease, and immunosuppression.[153]

Food particles may physically obstruct small or even large central airways, with the expected alterations in lung volume in segments distal to the obstruction. In addition, certain foods may cause severe local inflammatory changes. Bacterial contamination of the upper gastrointestinal tract secondary to bowel obstruction or even antacid administration greatly increases the risks of respiratory infection following aspiration.

Patients who have eaten shortly before intubation (<6 hours) should be assumed to

have a full stomach. In addition, those with bowel obstruction, pharyngeal or upper gastrointestinal bleeding, trauma, or acute onset of illness within 6 hours of eating and those who are pregnant or who have ileus or tense abdominal distention from any cause should be considered to have a full stomach.

Although delaying airway manipulation might be the measure most certain to prevent aspiration, this approach is not a realistic option in most situations confronting the intensivist. In a conscious child, the volume of gastric contents can be minimized by suction through a relatively large-gauge nasogastric tube, but complete emptying of the stomach, particularly of large food particles and blood clots, is rarely possible. Although H_2 antagonists and proton pump inhibitors (PPIs) effectively decrease both the volume and acid content of gastric secretions, an adequate effect requires 60 to 90 minutes following administration of these agents. Antacid, H_2 blockers, and PPIs do not decrease the volume of gastric contents already present in the stomach. Anticholinergic agents such as atropine or glycopyrrolate also reduce gastric acidity but slowly and less effectively than the H_2 antagonists. In addition, they may decrease gastroesophageal sphincter tone and appear to have no value in preventing the acid aspiration syndrome.

Antacids can effectively neutralize gastric pH. However, when aspirated, particulate antacids (aluminum and magnesium hydroxides) produce inflammatory changes as severe as gastric acid and food particles. Clear antacids, such as sodium citrate or Alka-Seltzer, appear to provide true protection. They effectively increase gastric pH and, when aspirated, appear to produce damage no more severe than that caused by normal saline solution. However, their use has not become common clinical practice.[154]

Intubation is at once protective of the patient vulnerable to gastric aspiration and itself a risk to the patient. In an alert child with intact protective airway reflexes, it may be appropriate to pass a nasogastric tube to decrease the volume of gastric contents. A clear antacid (eg, sodium citrate, 10 to 30 mL) can be administered orally or through the tube, which then is removed. In a child with impaired reflexes, no effort to pass a nasogastric tube should be made because of the risk of inducing vomiting or regurgitation with subsequent aspiration.

The intensivist should examine the patient's airway to be as certain as possible that intubation will not be difficult, as discussed previously. If intubation likely will be straightforward, a rapid-sequence intubation is indicated (Box 129.4). The goal of this method of intubation is to minimize the likelihood of vomiting or regurgitation and the time between loss of protective reflexes and correct positioning of the endotracheal tube. The sequence consists of preoxygenation, administration of an intravenous sedative or anesthetic with immediate cricoid pressure, pharmacologic paralysis, and endotracheal intubation. Properly applied, cricoid pressure probably decreases the likelihood of insufflation of gas into the stomach or regurgitation of gastric contents into the trachea and may improve visualization of the larynx (see Fig. 129.9).[103,155-157] On the other hand, excessive pressure may actually increase the likelihood of vomiting, occlude the trachea, or make visualization more difficult.

Box 129.4

Rapid-Sequence Intubation for Full Stomach

Indications

Food intake <4 to 6 hours before intubation

Pharyngeal or upper gastrointestinal bleeding

Intestinal obstruction or ileus (includes acute onset of illness)

Tense abdominal distention

Pregnancy

Relative Contraindications

“Difficult” airway

Profuse hemorrhage obscuring visualization

Upper airway obstruction

Increased intracranial pressure

Procedure

Prepare *all* necessary equipment, including suction devices

Allow patient to breathe 100% oxygen for 3 minutes

Direct assistant to apply cricoid pressure

Rapid intravenous infusion of anesthetic or sedative/analgesic and neuromuscular blocking agents

Allow patient to continue to breathe oxygen until apneic

Avoid manual ventilation to minimize gastric distention

Perform laryngoscopy and orotracheal intubation with stylet in endotracheal tube

Confirm endotracheal tube placement

Release cricoid pressure

The patient spontaneously breathes 100% oxygen by mask for 3 to 5 minutes before further manipulation. If the child can cooperate and has relatively normal gas exchange, four deep breaths provide a reasonable pulmonary reservoir of oxygen. However, in patients with severe pulmonary parenchymal disease, improvement in oxygenation may be limited and require a longer period of oxygenation.[158] If other factors in the child's condition permit, next steps in the rapid sequence intubation should be delayed until hemoglobin saturation reaches 100% or oxygenation reaches a plateau. Once preoxygenation is complete, the anesthetic or sedative is

administered by rapid intravenous infusion, an assistant applies cricoid pressure immediately, and, as consciousness is lost, a muscle relaxant is given. The mask supplying oxygen is kept in place until the patient becomes apneic, but no effort to assist ventilation is made in order to avoid gastric distention and regurgitation. Once the patient is flaccid and apneic, the intensivist performs laryngoscopy and intubates the patient. Use of a stylet in the endotracheal tube facilitates rapid intubation. Only after correct tube position is verified and the tube cuff, if present, is inflated should cricoid pressure be relieved and manual ventilation begun. In the case of unexpected difficulty intubating the patient and evidence of progressive hypoxemia, manual ventilation between attempts may be necessary but should be done with continued cricoid pressure.

The classic combination of drugs used for rapid sequence induction/intubation is sodium thiopental (4 to 6 mg/kg) and succinylcholine (1 to 4 mg/kg) with a prior defasciculating dose of a nondepolarizing muscle relaxant such as vecuronium. In the absence of thiopental, alternative drugs include ketamine or a benzodiazepine alone or in combination with a short-acting narcotic. As previously discussed, etomidate has been a popular agent, but growing evidence suggests its use is inappropriate in patients with shock, especially with presumed sepsis. Succinylcholine has multiple undesirable adverse effects (as noted previously) that may include increased intragastric pressure. Most of the nondepolarizing relaxants, when given in amounts two to three times the usual intubating dose, produce good conditions for intubation nearly as quickly as does succinylcholine (60 to 90 seconds) and without adverse effects, but lasting longer. Rocuronium is the current best alternative, with its rapid onset and relatively short duration of action. Table 129.3 lists suggested drugs and doses.

Increased Intracranial Pressure and Neurologic Dysfunction

The intensivist is frequently called on to intubate children with severe central nervous system dysfunction resulting from infection, hemorrhage, trauma, hydrocephalus, or mass lesions, any of which may be associated with actual or imminent intracranial hypertension and herniation. In most circumstances the intensivist can observe signs of elevated ICP or recognize settings where the likelihood is high, but there is no clinical measure of its severity. Current guidelines recommend intubation for patients with a Glasgow Coma Scale score of 8 or less.[159] Intubation under these conditions should be undertaken with the recognition that it is a likely stimulus for further and potentially lethal intracranial hypertension. The most immediate means of lowering ICP involves decreasing CBF (volume) through hyperventilation. Unfortunately, the process of intubation likely will decrease minute ventilation and increase cerebral blood volume for this and other reasons, as previously discussed.

Under normal circumstances, CBF is closely coupled to the cerebral metabolic oxygen requirement ($CMRO_2$). Cerebral oxygen consumption and blood flow increase with increasing body temperature, motor activity, pain or other noxious stimuli, and seizure activity. Blood flow also increases rapidly when PaO_2 falls below 50 to 60 mm Hg and linearly as $PaCO_2$ increases over a wide range. With intact

autoregulation, blood flow is independent of systemic blood pressure except at very high or low levels. However, when autoregulation is impaired, mean arterial pressure may affect CBF over a much broader range. Elevated intrathoracic pressure during struggling, coughing, or Valsalva maneuvers may impede jugular venous drainage and result in intracranial venous congestion.

Laryngoscopy and intubation are powerful noxious stimuli. In the awake unsedated child and even in the severely obtunded patient, laryngoscopy and intubation likely will precipitate vigorous struggle, coughing, pain (anxiety), and marked evidence of autonomic stimulation.[28,41,42,160] In most patients, sympathetic discharge predominates with tachycardia, hypertension, and diaphoresis. In the infant, vagal stimulation often predominates with resulting bradycardia.

Even in the lightly anesthetized patient, laryngoscopy itself and then intubation are associated with hypertension, tachycardia, and increased ICP. As might be predicted, massive surges in ICP are more likely to occur in patients suspected of having borderline or high baseline ICP before intubation than in those with intracranial pathology with well-compensated or previously controlled pressure. Arterial hypertension may precipitate further hemorrhage in the child with a vascular malformation, coagulopathy, or bleeding into a tumor. ICP waves may reduce cerebral perfusion pressure to ischemic levels or cause frank herniation.

Given the risk of life-threatening systemic and intracranial hypertension in these patients, it is clear that laryngoscopy and intubation should be undertaken with every effort to minimize stimulation and associated struggle.[105,161-163] In general, this implies ensuring excellent oxygenation, ventilation, and intubation under protection of profound sedation or anesthesia, with the assistance of neuromuscular blockade (Box 129.5). Neurologists and neurosurgeons are frequently loath to relinquish the opportunity to examine the patient following intubation, but the risk of life-threatening intracranial hypertension justifies temporarily obscuring the neurologic examination. In most cases, adequate assessment is possible before intubation, and diagnostic studies require deep sedation for a period afterward.

Box 129.5

Intubation for Increased Intracranial Pressure

- Prepare equipment
- Monitor heart rate, blood pressure, and arterial oxygen saturation
- Provide 100% oxygen and assisted ventilation as tolerated by patient
- Consider possible difficult airway
- If no airway contraindications, administer anesthetic and neuromuscular blocking agents
- No associated cardiovascular compromise or hypovolemia:
- Midazolam (0.2–0.3 mg/kg IV) and fentanyl (5–10 μg/kg IV) plus

lidocaine (1–1.5 mg/kg IV) and rocuronium (0.6–1.2 mg/kg IV) or other relaxant; consider etomidate (0.3 mg/kg IV)

- Concern for associated cardiovascular compromise or hypovolemia

- Consider omitting benzodiazepine

- Thiopental (4–6 mg/kg IV) plus lidocaine (1 mg/kg IV), plus rocuronium (0.6–1.2 mg/kg IV) or other relaxant

- Ventilate patient until drug effect achieved (consider short-term hyperventilation in patients with signs of critically elevated intracranial pressure)

- Perform laryngoscopy and orotracheal intubation

IV, intravenous.

The patient is provided 100% oxygen by bag and mask. An anesthetic or sedative agent in combination with a neuromuscular blocking agent is given, and manual ventilation is initiated to lower ICP as much as possible before airway manipulation. Although extreme hyperventilation may decrease CBF to ischemic levels, current guidelines support ventilation to a $PaCO_2$ of approximately 30 to 35 mm Hg for patients with intracranial hypertension.[164]

In the hemodynamically stable patient, relatively deep anesthesia is associated with a decline in $CMRO_2$, CBF, and ICP, provided that oxygenation and ventilation are well maintained.[161,163] Agents include narcotic analgesics alone or in combination with a benzodiazepine. Although the hemodynamic effects of narcotics (typically fentanyl) are usually modest, the effect on $CMRO_2$ is also limited unless given in anesthetic doses. Addition of a benzodiazepine further decreases $CMRO_2$ but may be associated with hemodynamic instability, especially in hypovolemic trauma patients.

Etomidate is widely used in patients with suspected intracranial hypertension. Its ability to decrease CBF without apparent detrimental effect on systemic hemodynamic stability makes it a useful agent, although concerns about its effect on adrenal function, perhaps even following a single dose, require caution in the patient with sepsis or shock. Because it lacks analgesic properties, combining it with an intravenous narcotic agent should be considered.

Lidocaine, 1 to 1.5 mg/kg, decreases $CMRO_2$ and modestly decreases the systemic and intracranial hypertensive response and the cough reflex, as long as a dose below the seizure-producing threshold is used. Effective serum concentrations are obtained more quickly and at lower doses by the intravenous route than when the agent is administered endotracheally. The available literature addresses patients fully premedicated and monitored undergoing neurosurgical procedures or patients already intubated, ventilated, and monitored in the ICU. Studies addressing intubation in the acute setting are lacking and unlikely to be accomplished.[164-168]

Although the classic recommendation has been to avoid ketamine in patients with elevated ICP because of its potential to further increase pressure, newer studies suggest that ketamine may be safe in this population. It does, however, increase

systemic blood pressure and CBF and most likely should be avoided in patients at risk of failed autoregulation until further evidence is available.[89-90,169-171] In addition, evidence that ketamine is associated with neuronal injury in immature animal models supports continued caution with respect to its use in patients with elevated intracranial pressure.

In nearly all patients, orotracheal intubation is preferred because it is accomplished quickly and easily with less risk of prolonged manipulation and interrupted ventilation. Nasotracheal intubation is contraindicated in patients with basilar skull fractures and CSF leaks as a potential source of infection or even perforation of the cribriform plate and intracranial tube placement.

Cervical Spine Instability

Flexion and extension of the head on the neck occur between the atlas (C1) and the basiocciput. Rotation occurs between the atlas and axis (C2), as the thin arch of the atlas pivots around the odontoid process. Below the axis, the cervical vertebrae articulate with each other anteriorly at the intervertebral discs and posteriorly at the facet joints. Further neck flexion and extension occur at these joints. Anterior and posterior ligaments complete the stable spine.

Spinal cord injury generally occurs as a result of bony fracture, compression, or disruption of cervical ligaments. In young children, actual ligamentous disruption or bony fracture is not necessary for severe cord injury, even transection, to occur; extreme stretching, as may occur in acceleration or deceleration injury, is sufficient.[172-174] Instability results from disruption of both the anterior and posterior columns. Congenital or degenerative anatomic abnormalities, penetrating wounds, or expanding mass lesions in the spinal canal may compromise cord integrity.

During routine intubation, the intensivist flexes the neck and extends the head. In children with known or suspected cervical spine injury or instability resulting from other causes (eg, Down syndrome or rheumatoid arthritis), manipulating the head and neck for intubation risks extending the existing condition or injury and may precipitate new problems. Cervical spine films and knowledge about the nature of the traumatic event help define the precise injury and predict maneuvers most likely to do harm, but such information rarely is complete and may be falsely reassuring.

The ideal approach to intubation in this setting is controversial.[175-178] Although evidence in cadavers, in addition to common sense, indicates that typical airway maneuvers can cause anterior or posterior subluxation or widening of the disc space, evidence in patients is lacking.[179] Axial traction increases distraction and even subluxation in some patients[179]; in others traction is helpful. However, information about the appropriate amount of force or the correct plane in which it should be applied is rarely sufficient to make a timely informed decision. Therefore immobilization of the head and neck in the midline without traction is recommended.[180]

Current advanced trauma life support guidelines no longer recommend blind nasotracheal intubation.[181,182] Orotracheal intubation is more reliably accomplished and less time consuming than blind nasotracheal intubation and is associated with far fewer complications, including tube malposition and bleeding, even in adults.[183] The high anterior location of the pediatric larynx makes nasotracheal intubation even more difficult in young children. As a result, it is rarely a necessary or desirable

choice for emergency airway stabilization in children.

Just as manipulation of the airway for intubation may risk additional cord injury, patient movement can cause additional damage. Few children of any age will tolerate awake intubation by any route without violent struggle. Even heavily sedated patients likely will cough upon stimulation of the airway.

Patients with spinal cord injuries are at risk for extreme hyperkalemia and resulting dysrhythmias or cardiac arrest following administration of succinylcholine. This response occurs from approximately 48 hours to 6 to 9 months after injury. Cervical injury often also disrupts sympathetic nervous system outflow and results in unopposed vagal tone and severe bradycardia. For these reasons, in most instances intubation is best accomplished in these patients via the orotracheal route, using an intravenous anesthetic or combination of sedative and analgesic agents, atropine, and a nondepolarizing neuromuscular blocking agent with an assistant immobilizing the head and neck in neutral position with one hand over the ear on each side of the head. If time, equipment, and available expertise permit, fiberoptic bronchoscopy may assist visualization of the larynx and intubation with minimal head or neck movement.[184] Video laryngoscopy has been helpful in adults, but experience is limited in children.

If orotracheal or nasotracheal intubation cannot be accomplished because of associated facial or airway injuries or other technical obstacles, cricothyrotomy or primary tracheotomy may be indicated. However, no data support either the necessity or safety of routinely using a surgical approach before attempting orotracheal intubation.

Upper Airway Obstruction

Upper airway obstruction may result from many disorders (see Chapter 50). When symptoms are related to loss of oropharyngeal muscle tone, changing the patient's position, reversing the effects of a drug, or placing a nasal airway may be sufficient, if the duration of the underlying process likely will be brief. However, when airway structures likely are severely or progressively distorted by edema, inflammation, trauma, or another space-occupying process, achieving an endotracheal airway is necessary.

Patients should be allowed to assume whatever position is most comfortable. Supplemental oxygen is provided at the maximum concentration possible, but a young child's anxiety should not be heightened with an overly aggressive approach with a mask. Contrary to popular belief, breathing can be assisted in nearly all cases by application of positive pressure, initially with continuous positive airway pressure and then gradually with assisted breaths.

In general, no action should be taken that compromises the child's ability to breathe spontaneously until the capacity to control ventilation is certain. In particular, use of neuromuscular blocking agents is dangerous and inappropriate until after the airway is controlled. Distortion of the airway may be so extreme that recognition of landmarks for intubation is impossible, and loss of pharyngeal tone in such patients may remove the last barrier to complete airway occlusion. However, reducing a child's anxiety with cautious sedation (with a reversible agent) may decrease peak inspiratory flow rate and symptoms of obstruction and make it easier to assist breathing and establish an artificial airway. When possible the child is

gently lowered to a supine position (or to 30 degrees) and intubated by the orotracheal route. When time and available expertise permit, intubation in the operating room using an inhalational anesthetic in a high oxygen concentration allows spontaneous breathing until the patient is deeply anesthetized and untroubled by airway manipulation. This method may be especially helpful in cases of supraglottitis. In most cases, the proper tube size is 0.5 to 1 mm smaller in diameter than predicted for age because of airway inflammation and edema, and no leak will be present.

Extubation usually is well tolerated when a leak has developed.

Facial and Laryngotracheal Injury

Children with facial injuries present airway problems nearly as varied as the injuries themselves. Appropriate management depends primarily on accurate assessment of airway patency at presentation, the rate of bleeding (if any) into the airway, and the amount of additional swelling and distortion likely to occur later. Evaluation of possible ocular and intracranial injury must proceed simultaneously.

Profuse bleeding, unstable facial fractures, or aspiration of blood, gastric contents, or teeth causes early respiratory distress. Maxillary fractures may result in a free-floating maxilla with occlusion of the nasopharynx and pressure on the tongue. Isolated mandibular fractures often cause trismus but rarely cause airway obstruction or interfere with visualization of the larynx.

Airway management begins with suctioning blood and debris from the mouth and pharynx. If permitted by other injuries, the child is placed with the head down and turned to the side. The tongue and maxilla are pulled forward manually if necessary. A spontaneously breathing patient receives oxygen by mask and may not require further intervention before surgery. Patients with persistent obstruction may require an immediate artificial airway.

In most cases, orotracheal intubation is accomplished first. If ventilation can be assisted with bag and mask and bleeding is controlled, the patient may be sedated, paralyzed, and intubated with full stomach precautions. If bag-mask ventilation exacerbates airway obstruction, awake intubation may be necessary. Uncontrollable bleeding, inability to visualize the larynx, or violent struggle in a child with cervical spine instability or evidence of increased ICP may make a primary tracheostomy desirable. Nasotracheal and nasogastric tubes are avoided until the possibility of a basilar skull fracture and CSF leak is eliminated.

Laryngotracheal injuries may be subtle or dramatic. They should be suspected in children with a history of anterior neck trauma and often cause hoarseness, stridor, subcutaneous emphysema, pneumothorax, or pneumomediastinum. Aerosolized epinephrine may temporarily decrease swelling and provide a little extra time to evaluate the airway and plan intervention. Awake intubation with cautious sedation and topical anesthesia that is conducted under direct vision by laryngoscopy or fiberoptic bronchoscopy minimizes the risk of sudden, complete obstruction or creation of a false passage adjacent to the airway.

Open Globe Injury

Children with penetrating eye injuries may require emergency intubation for

respiratory failure resulting from associated injuries or other underlying problems. Management in these cases seeks to prevent increased intraocular pressure with subsequent extrusion of the vitreous and permanent blindness. Intraocular pressure can be increased by struggling, crying, coughing, straining, or rubbing the eye. Hypoxia and hypercarbia can increase intraocular pressure. In general, central nervous system depressants lower intraocular pressure, with the possible exception of ketamine. Intubation should be performed smoothly under full muscle relaxation if possible, taking into consideration associated injuries and the risk of a full stomach.

The child should be preoxygenated with 100% oxygen, taking care not to apply pressure to the eye with the mask. Efforts to empty the stomach are delayed until the patient is fully relaxed and intubated. In hemodynamically stable patients, rapidly acting sedatives or anesthetics are administered, followed by a nondepolarizing neuromuscular blocking agent if other airway anatomy permits. Succinylcholine, a depolarizing relaxant, has been associated with increased intraocular pressure, even in the absence of fasciculations. As in patients with head trauma, a combination of sedative and analgesic agents may replace thiopental if hemodynamic stability is uncertain. Lidocaine supplements the effect of other agents in blunting the rise in intraocular pressure that may occur even during a smooth intubation. Heavy sedation or paralysis should be maintained following intubation until after repair.

Alternative Approaches to the Airway

Lighted Intubation Stylet (Light Wand)–Assisted Intubation

A number of lighted intubation stylets have become available. Each uses transillumination of the neck to guide placement of an endotracheal tube. The devices consist of a handle containing the power source and a malleable wand (stylet) with a light at the tip. Pediatric versions accommodate tubes as small as 3.5 mm.

Use of the lighted stylet for intubation is a technique recommended for use in patients with airways that are difficult to manage. Reported experience in children is limited, but the technique has been successful in the hands of both highly skilled and novice operators.[185-189] The equipment is fairly simple to use and easy to learn. It does not require visualization of the airway, is less stimulating than laryngoscopy, allows nasal or oral intubation, and is portable and relatively inexpensive. Reported series indicate that mucosal and dental injuries are uncommon, and sore throat is less of a problem than following standard laryngoscopy.[190] Because intubation may be accomplished from the patient's side, it may be useful in awkward settings such as emergency transport vehicles.

Potential disadvantages include trauma to the upper airway and larynx. Anything that obscures transmission of light through the anterior neck interferes with its use, including scarring, massive edema, subcutaneous emphysema, or mass lesions. Profuse bleeding or thick airway secretions that obscure the bulb also interfere with effective use.

A lubricated lighted stylet is inserted through an endotracheal tube of desired size until the light is just short of the end of the tube, and the tube is firmly attached. The

tube and stylet are bent to approximately 90 degrees, just proximal to the cuff if present. Dimming the room lights improves appreciation of the transillumination. The intubator may stand at the head of the bed or to the side of the patient. The head is extended. A shoulder roll may be useful. The intubator pulls the mandible and tongue forward and upward, and the styletted tube is introduced into the patient's mouth in the midline. It is advanced into the pharynx, while the operator observes transillumination of the soft tissues of the neck. Entry into the airway typically is recognized by the presence of a focused glow of light in the midline below the thyroid prominence; more diffuse light suggests esophageal placement. The tube is advanced until the light is at the level of the sternal notch. The lighted stylet is withdrawn and tube placement is confirmed with capnography.

Nasal intubation is possible with the light wand. In this case, the trocar is removed to increase the flexibility of the device. When a glow is noted above the thyroid prominence, the tube is likely in the vallecula. The epiglottis can be moved out of the way with a jaw thrust, allowing further advancement of the tube into the trachea. An alternative is to flex the patient's neck, as is sometimes necessary with visualized nasotracheal intubation.

Laryngeal Mask Airway

The laryngeal mask airway (LMA) is a relatively new and fairly safe means of securing a difficult to manage airway in an infant or child.[191-193] It was designed to provide a supraglottic airway device that would offer the benefit of noninvasive ventilation. Its use rapidly gained acceptance in anesthesiology and has been incorporated into the American Academy of Anesthesiology difficult airway algorithm.[52] It consists of a small mask with an inflatable rim and a tube with a universal adaptor, which permits attachment to a resuscitation or anesthesia bag or ventilator (Fig. 129.11). The original LMA consists of a wide-bore tube designed to sit in the hypopharynx and is attached to an inflatable bowl-shaped base that bypasses the tongue, sits around the epiglottis, conforms to the shape of the larynx, and provides a low-pressure seal around the supraglottic area.[194] The LMA is available in a wide range of sizes, allowing use in very small infants to very large adolescents and adults. Choice of LMA size is based on weight: size 1 for patients weighing 2.5 to 6 kg, size 2 for patients weighing 6 to 30 kg, and size 3 for patients weighing more than 30 kg.[195,196] Since the initial development of the LMA, several other types have been designed, including the flexible LMA, intubating LMA, disposable LMA, and ProSeal LMA, not all of which are available in pediatric sizes.[197]

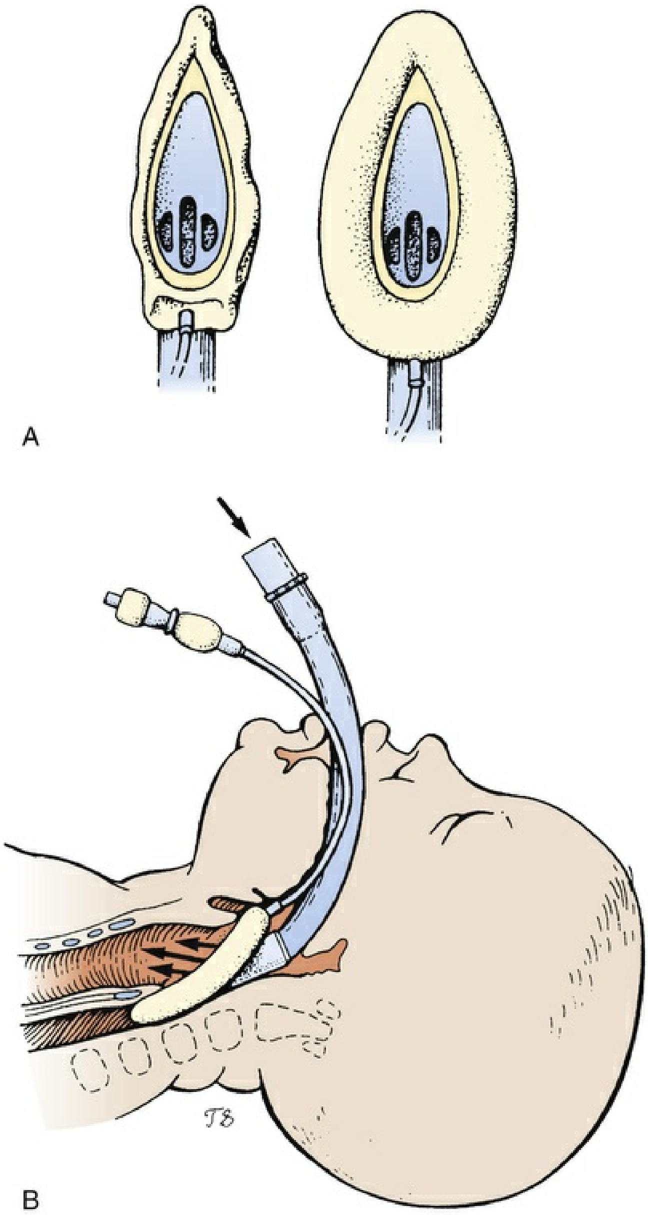

FIG. 129.11 LMA. (A) Mask portion of the airway with the rim deflated for insertion *(left)* and inflated *(right)*. (B) LMA in position, with the rim inflated around the laryngeal inlet. (From Efrat R, Kadari A, Katz S. The laryngeal mask airway in pediatric anesthesia: experience with 120 patients undergoing elective groin surgery. J Pediatr Surg 1994;29:206.)

The insertion technique can be learned quickly by physicians and other providers, including emergency transport personnel, often more quickly than endotracheal intubation. Experience with a mannequin appears to be effective training. Once in place, the LMA can serve as a means of ventilating the patient until the desired definitive airway can be established. It can facilitate subsequent tracheal intubation, if desired, either with blind technique or via fiberoptic bronchoscopy.

Insertion of the LMA does not require muscle relaxation or the use of a laryngoscope and is therefore considered a blind technique. Topical anesthesia, with lidocaine spray or lidocaine jelly applied to the inflatable rim, is helpful in patients with intact protective airway reflexes who are awake. With the rim deflated or partially inflated, the LMA is advanced along the posterior pharyngeal wall with the

dorsum of the mask facing the palate until resistance of the upper esophageal sphincter is encountered. The cuff is then inflated, forming a seal around the laryngeal outlet, and the attached tube is connected to a source of oxygen and positive pressure (Fig. 129.12).

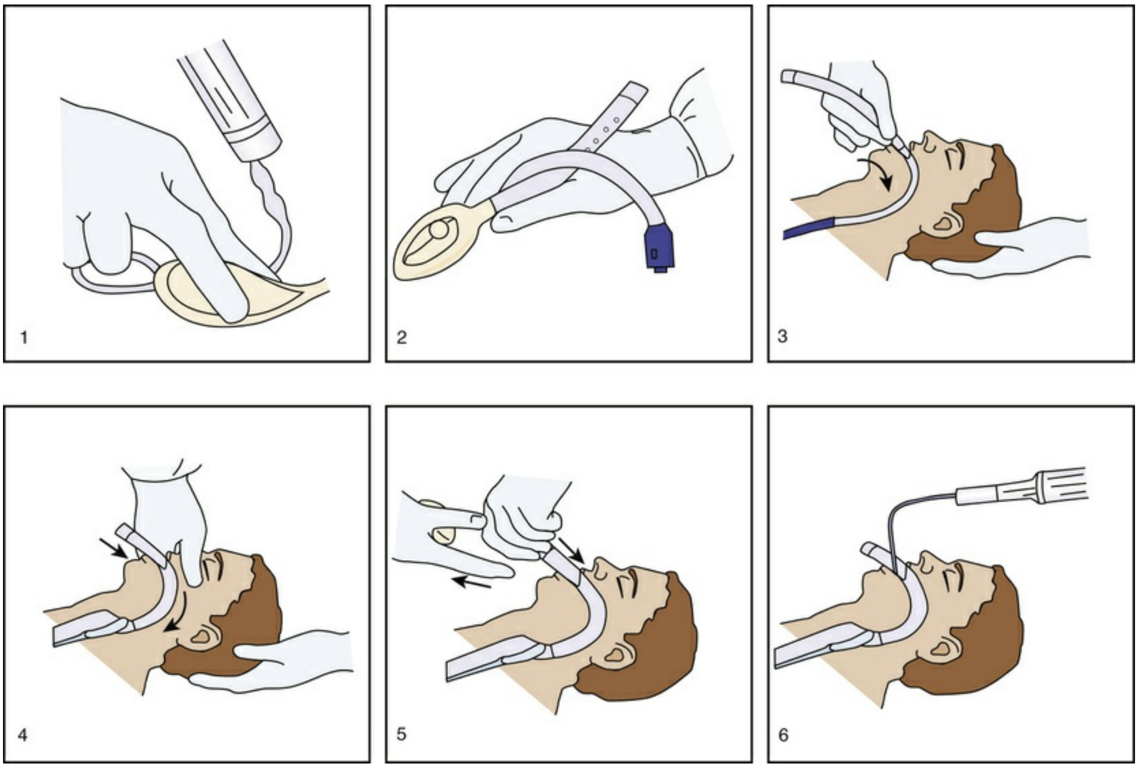

FIG. 129.12 Inserting the LMA. Preoxygenate the patient as necessary. *1,* Deflate the cuff against a flat surface with index finger and middle finger on either side of the bowl. *2,* Hold the LMA like a pen, with the index finger at the junction of the tube and mask. *3 and 4,* Insert the LMA into the mouth and advance, following the palate and posterior pharyngeal wall until resistance is met. *5,* Let go of the mask and tube. *6,* Inflate the cuff, allowing the device to move into correct position. (Adapted from Ambulance technician study, http://www.ambulancetechnicianstudy.co.uk/.)

Proper placement is essential but is most uncertain in infants requiring the LMA size 1, most likely because the margin of error for placement in the small pharynx is so small. In general, the risk of downfolding the epiglottis, thus occluding the trachea, is greater in children than in adults. Successful placement depends on the shape and tone of the pharynx, adequate matching of the cuff, the palatopharyngeal curve and shape of the posterior pharynx, the extent to which anterior structures (such as tonsils) obliterate the curve, the position of the head and neck, the efficacy of digital manipulation, and the depth of anesthesia/sedation, muscle relaxation, or loss of airway reflexes.[194] Tissue trauma is uncommon, and the need to manipulate the cervical spine during placement is minimal. In most patients the autonomic response to placement is less pronounced than with laryngoscopy and intubation. On the other hand, the device does not fully protect against aspiration in the setting of a full stomach. In addition, it may not be effective in patients with glottic or subglottic pathology.

Although its primary use is in the operating room, growing experience demonstrates that the LMA can be lifesaving in a variety of other settings when no other nonsurgical means of maintaining an airway is successful, particularly in patients with anatomically abnormal airways.[198] Success with airway management in the operating room with children with airways that are anticipated to be difficult to manage, including patients with Pierre Robin, Treacher Collins, and Goldenhar syndromes, suggests that the LMA would be valuable for managing such patients in emergency settings such as the emergency department or ICU. The ease and rapidity of insertion and decreased gastric air insufflation during resuscitation make it a valuable tool when intubation fails during adult resuscitation.[199] Pediatric Advanced Life Support incorporates the LMA as an effective alternative to intubation during resuscitation when inserted by trained providers.[200] In neonatal resuscitation, when facemask ventilation or intubation is not successful, the LMA provides a means of rapidly improving oxygenation and heart rate. It is not, however, effective for aspirating meconium and may be inadequate for infants with severely noncompliant lungs. Use by prehospital personnel has been effective for critically ill adults, but experience in children in the field has not been reported.[201,202]

Patients with intact protective reflexes poorly tolerate the LMA, so its use is largely limited to those with severely depressed levels of consciousness or heavy sedation or anesthesia. Lidocaine jelly on the inflatable rim or lidocaine pharyngeal spray may promote tolerance in patients with active airway reflexes. A disadvantage with use of the LMA is the inability to use airway pressures greater than approximately 20 mm Hg to prevent air leaking around the mask and to avoid gastric distention, and therefore it is not an optimal airway device in patients with severe subglottic airway obstruction, parenchymal disease requiring high ventilatory pressures, or in obese persons.[203] It also is not the ideal technique to use in a patient with a full stomach because its design does not prohibit aspiration of gastric contents. However, in an emergency situation the benefit of providing oxygenation and ventilation via an LMA outweighs the risk of an aspiration event. Other scenarios that may limit placement of the LMA include excessive neck extension, limited mouth opening, or excessive application of cricoid pressure.[203]

Although the seal is somewhat protective, patients with a full stomach remain at risk for aspiration. Positive airway pressure should be minimized as much as possible and a nasogastric tube passed to decrease gastric distention. Cricoid pressure may further decrease the risk of aspiration but also may interfere with proper LMA placement. If desired, an endotracheal tube can be inserted through the mask, either blindly or with fiberoptic bronchoscopy.[204,205]

Tracheostomy

Indications for tracheostomy include structural abnormalities of the upper airway requiring surgery, laryngeal trauma or complex craniofacial injury, severe facial burns, congenital anomalies lacking surgical treatment, vocal cord paralysis, and iatrogenic injury to the upper airway. Severe chronic neurologic dysfunction with impaired protective reflexes is an additional indication. Even in the absence of evidence of upper airway damage, tracheostomy may be performed to provide a more comfortable airway, which simultaneously allows airway protection, respiratory support, and greater patient mobility so that nutritional, developmental,

and psychosocial needs may be met, especially, but not only, in patients undergoing chronic ventilation.[206-209]

Tracheostomy spares laryngeal and subglottic structures from the trauma of an artificial airway, particularly in active or thrashing patients. Tracheostomy tubes are less likely to be inadvertently dislodged or to become obstructed, but if either problem occurs early following tracheostomy, it is more likely to be catastrophic. Because the tube is inserted below the cricoid ring, it often is possible to use a larger tracheostomy tube than endotracheal tube. Nevertheless, a larger leak around the tube may interfere markedly with effective ventilation in patients requiring high airway pressures.

Complications in the early postoperative period include bleeding, subcutaneous air dissection, pneumothorax, pneumomediastinum, injury to the recurrent laryngeal nerve, and death, usually as a consequence of loss of control of the airway intraoperatively or an unrecognized complication from the preceding list. Nearly all pediatric patients can and should be intubated before tracheostomy. Prior intubation decreases the incidence of most technical problems. Exceptions include patients with complex facial or airway injuries or deformities and those in whom no other means of establishing an airway have been successful. Wound colonization occurs rapidly. Bacterial infection may occur, rarely involving major cervical and mediastinal structures. Swallowing difficulty is common and may result from the tube and fixation tapes limiting excursion of the larynx. Aspiration may result from alteration of the laryngeal closure reflex.

Tracheostomy tube obstruction or accidental dislodgment is suspected when the patient becomes agitated and shows signs of increased respiratory distress, a suction catheter no longer passes freely, manual ventilation is ineffective, or, in case of dislodgment, the child is suddenly able to vocalize. In such cases the tube should be removed and replaced with a new one. The child is placed supine with the head and neck extended. Oxygen is delivered to the nose, mouth, and tracheal stoma. If manual ventilation is necessary, the stoma can be occluded to allow bag-mask ventilation as previously described. A fresh tracheostomy tube is inserted, initially directly posteriorly and then caudad. Replacement with a smaller tube or endotracheal tube may be necessary if resistance is encountered. Resistance to passage of a suction catheter or ineffective ventilation following replacement of a tracheostomy tube, particularly in the first 7 to 10 days postoperatively, is highly suggestive of creation of a “false passage” in a tissue plane outside the tracheal lumen. Reestablishing tracheal cannulation may require surgical intervention. Life-threatening pneumothorax or pneumomediastinum occurs frequently in such patients.

Late complications include granuloma or stricture formation at the stoma or where the tip of the tube meets the tracheal wall. Persistent posterior wall pressure may cause tracheoesophageal fistula formation. Erosion into the innominate artery is another rare occurrence, usually when the tracheostomy incision is below the third tracheal ring. The importance of an experienced, well-trained staff immediately available to address problems is supported by data demonstrating that mortality related to tracheostomy is significantly lower when performed in a children's hospital and decreases with increasing volume.[210]

Decannulation occurs when the indications for tracheostomy are no longer present. Diagnostic laryngotracheobronchoscopy before a planned decannulation

permits identification of problems likely to interfere with effective breathing, including granulation tissue, severely stenotic areas, or vocal cord abnormalities. If none is present, the indwelling tube is replaced with successively smaller tubes until the smallest available is in place and the child is breathing well. If no distress occurs, the tube is removed and the stoma is covered.

Cricothyrotomy and Retrograde Intubation

Although airway management by endotracheal intubation is possible and endotracheal intubation is the appropriate first choice in the majority of pediatric patients, intubation is not possible or should not be done on certain occasions. Such situations include massive facial trauma, oropharyngeal hemorrhage or presence of a foreign body, or severe upper airway obstruction.[211] Cricothyrotomy is an alternative to tracheostomy for rapidly establishing an airway in apneic or severely distressed patients.

The child's head and neck are extended with a roll under the shoulders. The cricothyroid membrane is palpated between the inferior margin of the thyroid cartilage and the superior edge of the cricoid cartilage. With one hand (or an assistant) stabilizing the larynx and trachea, the clinician punctures the membrane in the midline with a large angiocatheter, withdraws the stylet, and connects the catheter to a source of oxygen using the connector to a size 3 endotracheal tube. Kits are available that facilitate cricothyrotomy using the Seldinger technique. Oxygenation is rapidly improved in spontaneously breathing patients, but carbon dioxide elimination is minimal. Transtracheal jet ventilation is effective through such catheters, provided that the upper airway permits passive exhalation; otherwise, severe hyperinflation and life-threatening barotrauma are certain.

Retrograde intubation can be accomplished by this approach. Once the cricothyroid membrane has been punctured and the catheter has been placed in the tracheal lumen, a long wire from a vascular access kit is advanced cephalad into the mouth. With the wire firmly secure, an ETT may be advanced into the trachea. Once the tube is in the tracheal lumen, the wire is withdrawn and the tube is further advanced into the desired position. If the wire is insufficiently stiff to permit passage of the tube into the trachea, an ETT exchanger can be advanced over the wire first, followed by the ETT.

In adults and adolescents, a small horizontal incision over the cricothyroid membrane is an alternative approach. Once the membrane is incised, it is spread vertically, and a standard tracheostomy or ETT is inserted into the tracheal lumen. This approach is not recommended in infants and young children except in highly skilled hands because of the potential for grave injury to a small, soft trachea or nearby neurovascular structures.

Complications are similar to those of tracheostomy. Complication rates of 10% to 40% are reported in adults.[184] Few experiences have been reported in pediatric patients, particularly in younger children.

CHAPTER 130

Anesthesia Effects and Organ System Considerations

Alison M. Jeziorski, Antonio Cassara, Peter J. Davis

PEARLS

- The anesthetic care of intensive care unit patients involves the extension of principles of medical management used in the operating room.
- The anesthesiologist caring for a critically ill child must have an understanding of the desired therapeutic end points and knowledge of the patient's preexisting condition.
- For the intensive care physician, a patient returning to the intensive care unit after surgery frequently requires an altered management plan. The physiologic perturbations of surgery and anesthesia frequently change the focus and direction of medical management. The intensive care physician must understand not only the events that occur in the operating room but also the rationale for using anesthetic agents and anesthetic techniques.
- Prompt recognition of the propofol infusion syndrome and discontinuation of the infusion are key to increased survival. Early administration of hemodialysis and perhaps even extracorporeal support improve survival.

Effects of Anesthetic Agents

Anesthetic agents have multiple physiologic effects and consequences in patients with underlying disease and trauma. Anesthetic agents have been associated with both organ protection and neurotoxicity.[1-3] Understanding the pharmacology of these anesthetic agents has significant implications not only for the operative management of the patient but also for postoperative recovery in the intensive care unit. This chapter focuses on the potent inhaled anesthetic agents, the frequently used intravenous sedative hypnotic agents (propofol and dexmedetomidine), the intravenous opioids, and the role of local anesthetic agents and their adjuncts.

Because these drugs have significant effects on cerebral neurophysiology and neurologic outcomes of patients, the pharmacologic discussion focuses on the drug's neurophysiologic effect.

Anesthetic agents affect myocardial performance. Historically inhalational anesthesia in children was associated with a higher rate of cardiac arrest, bradycardia, and hypotension in infants and children than in adults. These hemodynamic effects are dose related.[4-8]

Because it can be problematic to insert invasive monitors in unsedated, awake children, much of the information about the potent inhaled anesthetic agents and their effects on the determinants of cardiac output is derived from animal studies. Schieber and colleagues[9] observed that, although isoflurane reduced contractility and decreased blood pressure and systemic vascular resistance more than did equipotent concentrations of halothane, cardiac index was better preserved in the isoflurane-anesthetized animals. Thus when compared with halothane, the direct myocardial depressant effect of isoflurane is offset by its effect on the peripheral vasculature, which results in afterload reduction. Of note when comparing the anesthetic effects of inhalational agents, the concept of minimum alveolar concentration (MAC) is used as a metric. MAC is defined as the concentration that prevents movement of 50% of patients to a surgical incision. The use of MAC as a metric allows one to compare anesthetics of different potencies at a similar effect (MAC multiples) rather than comparing similar concentrations of drugs with different potencies.

Desflurane and sevoflurane are two potent inhalational anesthetic agents with low blood solubility coefficients. The low blood solubility affords rapid induction of anesthesia as well as rapid emergence and awakening.[10-15] Desflurane has a blood gas solubility coefficient (0.42) that is similar to nitrous oxide in children. However, desflurane's pungent airway properties result in a high incidence of laryngospasm, coughing, and hypoxemia if used as an induction agent in nonintubated children.[15] Significant increases in airway resistance have been reported in children with known reactive airway disease.[16] The cardiovascular profile of desflurane is similar for neonates, infants, and children.[13] Compared with awake values, anesthetized children have a 30% decrease in arterial blood pressure at 1 minimal alveolar concentration (MAC) of desflurane with a minimal change in heart rate. At equipotent concentrations (1 MAC), desflurane, isoflurane, and halothane all attenuate the baroresponse in children. In adults Weiskopf and associates[17] demonstrated that rapid increases in desflurane from 0.55 to 1.66 MAC produce a transient increase in arterial blood pressure and heart rate. This cardiovascular excitation is associated with an increase in sympathetic and renin-angiotensin system activity. Desflurane is not metabolized but is eliminated by ventilation. Because of its low solubility, emergence from anesthesia is rapid; however, even with its rapid elimination, former premature infants are still at risk for postoperative apnea.[18]

Sevoflurane is the most commonly administered anesthetic for children. As opposed to desflurane, sevoflurane is not an airway irritant and as such it can promote a rapid and smooth induction of anesthesia. Sevoflurane does undergo metabolism to a small extent and is metabolized by the 2E1 P-450 enzyme system to isopropyl alcohol and inorganic fluoride.[19] Recovery from sevoflurane is rapid; however, in children it has been associated with a high incidence of emergence

delirium (ED). Kuratani and Oi[20] in a meta-analysis found an increased probability of the emergence delirium with sevoflurane when compared to halothane. Martin and others have noted that children with ED exhibit arousal with delirious behavior accompanied by a variety of electroencephalogram patterns during the indeterminate state (ie, the state before the appearance of normal wake or sleep patterns). The electroencephalogram in children without ED progressed from the indeterminate state to classifiable sleep or drowsy states before peaceful awakening. Significant differences were also noted in frontal lobe functional connectivity between children with and without ED after the termination of sevoflurane anesthesia.

The hemodynamic profile of sevoflurane in children is similar to isoflurane. In adults anesthetized with sevoflurane or isoflurane, administration of exogenous epinephrine had similar dysrhythmogenic properties.[21] In an echocardiographic study of children comparing sevoflurane and halothane at equal MAC, Holzman and coworkers[22] noted that sevoflurane had fewer myocardial depressant effects than sevoflurane.

Because inhalational anesthetics can produce significant hemodynamic changes in compromised children, the use of high-dose opioids has been shown to confer hemodynamic stability and adequate anesthesia.[19-21] Robinson and Gregory,[23] in a study of premature infants undergoing patent ductus arteriosus ligation, reported the safety and efficacy of high-dose fentanyl anesthesia. In subsequent reports on pediatric patients, Hickey and Hansen[24] documented the safety of high-dose fentanyl and sufentanil in children with complex congenital heart disease. These investigators found that high doses of fentanyl (75 μg/kg) and sufentanil (10 μg/kg) decreased heart rate (7%) and mean arterial pressure (MAP, 9%). Pulmonary vascular resistance decreased and transcutaneous oxygenation increased by 45 to 100 mm Hg.

Though high-dose opioids produce hemodynamic stability in compromised infants and children, they prolong both recovery and respiratory depression.[25-27] Because fentanyl and sufentanil undergo hepatic elimination, repeated doses of the drug change its kinetic profile and increase its terminal elimination half-life. Opioids that do not rely on hepatic metabolism have the advantage of more predictable pharmacokinetic and pharmacodynamic control. Remifentanil is a synthetic opioid agonist that is metabolized by plasma and tissue esterases. It is independent of organ elimination. Consequently, it has an ultrashort half-life and a kinetic profile that does not change with the duration of infusion. Remifentanil's flat, context-sensitive half-time (elimination from the effect compartment) is not affected by the duration of the infusion. This contrasts with fentanyl and sufentanil whose pharmacokinetic profiles and context-sensitive half-times change drastically with duration of infusion (Fig. 130.1).

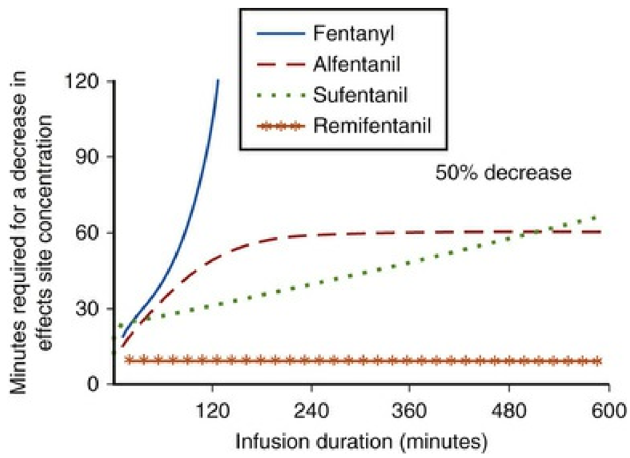

FIG. 130.1 Overlay of the fentanyl, alfentanil, and sufentanil recovery curves describing the time required for decreases of 50% from the maintained intraoperative effect site concentration after termination of the infusion. (From Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics, and rational opioid selection. Anesthesiology. 1991;74:53-63.)

Remifentanil's ultrashort half-life (7 to 10 minutes) coupled with its hemodynamic stabilization allows it to be titrated to a more predictable effect. Because it does not depend on organ elimination for its clearance, the pharmacokinetic profile of remifentanil in infants and neonates is quite different from that of other opioids. Remifentanil clearance is greatest in neonates and infants, and its terminal elimination half-life does not change with age.[28] This contrasts to the kinetic profiles of fentanyl, sufentanil, and morphine, which have lowest clearance and longest terminal elimination half-life in infants. In vitro studies by Olgatree and colleagues[29] have shown that remifentanil has no significant direct negative inotropic effect on the myocardium and that β-adrenergic stimulation of the heart remains intact. Comparative studies of remifentanil and inhaled anesthetic agents in children undergoing pyloromyotomy suggest that the short half-life of remifentanil may have beneficial effect on postoperative respiratory changes.[30,31] However, the rapid development of tolerance will likely preclude its use for longer periods of time.

Dexmedetomidine (DEX) is a sedative analgesic α_2-adrenergic agonist that is highly selective for the alpha 1 receptor (α_2/α_1 ratio of 1600 : 1). In addition to being used for sedation in pediatric ICU patients, it is also administered for invasive and noninvasive procedural sedation.[32,33] Stimulation of α_2 receptors in the central nervous system (CNS) and spinal cord produces sedation, anxiolysis, and analgesia. It also reduces anesthetic requirements for inhalational agents and opioids. In addition, DEX decreases renin and vasopressin levels, promotes diuresis, and reduces sympathetic tone, heart rate, and blood pressure.[34] As has been reported, bolus DEX infusions result in a biphasic blood pressure response (transient initial increase followed by a decrease). Within 1 to 2 minutes blood pressure returns to baseline while heart rate remains low. This biphasic effect is thought to be due to dexmedetomidine's initial ability to stimulate peripheral postsynaptic α_{2b}-adrenergic receptors resulting in vasoconstriction, followed by the more intense CNS effects on α_{2a}-adrenergic receptors causing sympatholysis. In a study of children undergoing routine surveillance endomyocardial biopsies after heart transplant, Jooste and coworkers administered a bolus dose (0.5 mcg/kg) of dexmedetomidine over 2 to 3

seconds. In this study, Jooste and coworkers noted that within 1 minute following injection, systolic blood pressure, diastolic blood pressure, systolic pulmonary artery pressure, diastolic pulmonary artery pressure, pulmonary artery wedge pressure, and systemic vascular resistance had all increased but returned to baseline by 5 minutes post injection. Only heart rate (HR) decreased following injection and remained below the baseline measurement after 5 minutes (the last recorded time point of the study). Cardiac output, central venous pressure, and pulmonary vascular resistance did not change significantly.[35]

The most common adverse events of DEX are hypotension and bradycardia, which are enhanced in the presence of cardiac comorbidities or when used with other medications that have negative chronotropic effects (propofol, succinylcholine, digoxin, pyridostigmine).[36-38] A loading dose of 1 mcg/kg over 10 minutes demonstrated an increased mean arterial blood pressure and decreased heart rate. This hemodynamic response was not maintained during an infusion of 0.7 mcg/kg/hr.[39] Bloor and coworkers[39] administered boluses of 0.25, 0.5, 1, and 2 μg/kg to healthy volunteers and noted a decrease in MAP, respectively, of 14%, 16%, 23%, and 27%. Cardiac output decreased 20% following a loading dose of 1 μg/kg in the first minute and returned to 90% of baseline after 60 minutes. When a loading dose of 2 μg/kg was administered, cardiac output decreased by 60% and returned to 85% of baseline after 1 hour. Venn and associates[41] studied the effects of dexmedetomidine in 66 patients with comorbidities who were in the ICU, who were mechanically ventilated, and who received a loading dose of 1 μg/kg followed by a continuous infusion of 0.2 to 0.7 μg/kg/hr. Hypotension and bradycardia (≥30% decrease from baseline) were observed in 18 of the 66 patients. Ingersoll-Weng also noted reports of bradycardia and sinus arrest.[37]

Khan and associates[42] reported similar effects of dexmedetomidine during anesthesia with isoflurane. The majority of the effects occurred with end-tidal isoflurane levels greater than or equal to 1%. Animal studies and studies on isolated human papillary muscle have demonstrated no direct negative inotropic effects on myocardial contractility.[43] Congdon and associates noted that in dogs, coadministration of intramuscular atropine with intramuscular DEX reversed HR changes. However, hypotension and arrhythmias (atrioventricular block, premature ventricular contractions, and bigeminy) were observed.[44]

Chrysostomou reported that DEX has antiarrhythmic effects in the perioperative period and suggested its possible use for terminating reentrant supraventricular tachycardia.[45-47] Muktar and associates reported sympatholytic effects of dexmedetomidine in pediatric patients.[48] Thirty infants and children undergoing CPB were randomized to receive dexmedetomidine (1 μg/kg load followed by a continuous infusion of 0.5 μg/kg/hr) or placebo. Plasma cortisol norepinephrine, epinephrine, and glucose levels were significantly lower in the dexmedetomidine group. Hammer et al has reported on the electrophysiological effects of dexmedetomidine in pediatric patients undergoing electrophysiology studies.[40]

Dexmedetomidine has a rapid distribution phase (6 minutes) and an elimination half-life of 2 hours.[49] Petroz and colleagues[50] demonstrated that children 2 to 12 years of age have similar pharmacokinetics to adults. Rodarte and associates[51] studied the pharmacokinetics in infants 1 to 24 months of age. He concluded that infants have a faster clearance of dexmedetomidine than adults (27 mL/kg/min versus 13 mL/kg/min). A loading dose of 1 μg/kg and continuous infusions of 0.2 to 0.7

μg/kg/hr have been used in various clinical scenarios to produce sedation-analgesia. Effects on respiration appear to be minimal. This may be beneficial in children with upper airway obstruction.[52]

Propofol is a sedative hypnotic that is widely used as an induction agent in anesthesia. It is also used as a continuous infusion for prolonged sedation in the ICU. Propofol is rapidly distributed and cleared. These properties allow for a relatively quick recovery. Propofol is suspended in a lipid emulsion, which when administered by a continuous infusion results in a significant lipid load. Induction doses for anesthesia vary from 2 to 3 mg/kg, whereas ICU sedation doses vary from 50 to 250 μg/kg/min. Induction doses of propofol can cause a 10% to 15% decrease of MAP as well as bradycardia, especially when coadministered with other vagotonic drugs. Propofol has a modest negative inotropic effect, due to antagonism of β-adrenergic receptors and calcium channels.[53] Propofol has many properties attractive for use in sedation. However, there have been increasing reports of a fatal adverse reaction that has been termed the propofol infusion syndrome (PRIS).[54] PRIS is characterized by severe intractable bradycardia that leads to cardiac failure, severe metabolic acidosis, hyperlipidemia, rhabdomyolysis with consequent hyperkalemia, and renal failure.[55-57] Prolonged propofol infusions (more than 48 hours) and infusion rates greater than 4 mg/kg/hr have been linked to PRIS. Priming factors such as critical illness (respiratory failure and traumatic brain injury) and triggering factors such as catecholamine and steroid infusion are associated with the syndrome.[58] The underlying mechanism appears to be an inhibition of mitochondrial electron transport and impairment in oxygen utilization.[53] As a result, there is a decreased ATP production and a decreased mitochondrial lipid metabolism, with an accumulation of toxic long fatty acid chains that are arrhythmogenic.[59-61] Pediatric patients appear more susceptible than adults secondary to low glycogen stores and high need for fat metabolism.[62] Management of PRIS is very difficult and consists of prompt recognition and interruption of the infusion. Aggressive cardiac resuscitation must be initiated early on with high-dose inotropes, fluid administration, and the use of pacing devices. The early administration of hemodialysis and hemofiltration together with extracorporeal membrane oxygenation has improved survival.[63-65]

Local Anesthetic Agents

The use of local anesthetic agents for regional anesthesia in infants and children has significantly improved pediatric pain management. Unlike in the adult population the majority of regional blocks done in infants and children are done under general anesthesia. Prospective and retrospective safety studies have demonstrated that performing these blocks under general anesthesia is a safe practice.[66-67] The use of ultrasound has become routine for the performance of regional blocks in pediatric and adult patients.[68-69] Direct visualization of the nerve, the needle, and the distribution of local anesthetics has improved the quality of the block, decreased the incidence of nerve injury secondary to direct nerve stimulation with the needle, especially when a preexisting neuropathy is present, and decreased the amount of local anesthetic necessary to produce an effective block.[70-73]

Local anesthetic agents are classified as amino esters (cocaine, tetracaine, chloroprocaine, and prilocaine) or as amino amides. The amino amides include

bupivacaine, ropivacaine, levobupivacaine, and lidocaine and are potent sodium channel blockers. At toxic blood concentrations they can cause seizures, cardiac arrhythmias, and cardiac arrest that can be resistant to resuscitation.[74,75]

Children are more at risk from local anesthetic toxicity because of their lower serum concentrations of α-1 acid glycoprotein (AAG) and albumin, which are the binding proteins for local anesthetics (LAs). Therefore the unbound fraction of LA, which is the active drug, is increased, making infants and children more susceptible to local anesthetic toxicity (LAST). Another factor that can influence LAST in neonates and children is the slower metabolism and elimination of the local anesthetic agents.[74,75]

The potency and duration of local anesthetic agents depend on lipophilicity, degree of ionization, protein binding, and the vasoconstricting properties of the drug. In general, the duration of action of local anesthetic agents is shortest in neonates and infants. Metabolism of amides is by the liver's P-450 enzyme system, whereas metabolism of the ester compounds is by plasma esterases (butyrylcholinesterase) and tissue esterases.

Ropivacaine 0.2% to 1% and levobupivacaine 0.1% to 0.5% are newer local anesthetic agents that are mainly used in pediatric regional anesthesia because of their favorable systemic toxicity profile. They have similar onset time and duration of nerve block when compared to lidocaine and bupivacaine.[76]

Even when weight-based dosing regimens are applied, LAST can occur and immediate diagnosis and treatment should be initiated. Neurotoxicity occurs before cardiac toxicity, and the signs (increased blood pressure and heart rate, muscle rigidity) can be difficult to distinguish from other causes in the anesthetized patient. Treatment with bolus infusions of lipid emulsions is now considered first-line therapy.[77] Dosing of Intralipid includes an initial dose of 20% Intralipid 1 to 1.5 ml/kg maximum of 10 ml/Kg[75] followed by an infusion of 20% Intralipid at 0.25 to 0.5 ml/kg/min. Airway management and basic life support are key elements for adequate resuscitation. It should be emphasized that although it is prepared in a lipid emulsion, propofol is contradicted in the resuscitation from LAST.

Systematic absorption of local anesthetic agents contributes to LA toxicity. Vascular areas are more prone to rapid absorption. The rate of absorption is greatest in the intercostal space and trachea followed by the caudal and epidural space and least in the subcutaneous tissue.

Adjuvants for local anesthetics are frequently administered in conjunction with the local anesthetic to prolong the duration, improve the quality of the block, and lower the concentration and dose of the administered LA.[78] Adjuncts are mostly used in neuraxial blocks and in particular for single injections in the caudal space. Preservative free opiates increase the duration of analgesia but have significant side effects (nausea, vomiting, pruritus, and sedation).[79] Clonidine, an alpha-2 adrenergic agonist, has also been administered as an adjunct in both peripheral and central nervous system blocks. However, there is weak clinical evidence to support the use of clonidine to prolong the duration of peripheral nerve blocks in children.[80]

Clonidine doses 1 to 2 ug/kg (bolus) and 0.1 ug/kg/h (continuous infusion) can increase the duration of a block by 3 to 5 hours. Dexmedetomidine, a more selective α-2-receptor agonist, at the same doses has a similar effect.[81] Other adjuvants such as midazolam, ketamine, neostigmine, and dexamethasone either have excessive side effects or show weak clinical data to support their use.[81] Although these adjuncts are

frequently used, at present there have been no toxicity studies demonstrating the safety of these agents on the central nervous system.

Two blocks (paravertebral and transverse abdominis) deserve mentioning because of their applicability for the pediatric intensive care unit (PICU) patient. The paravertebral block in the form of a bolus injection or a continuous infusion has become more popular now in the pediatric population with the use of ultrasound. It is a valid alternative to neuraxial blocks because it has fewer contraindications and complications. It is particularly indicated for thoracotomies, breast surgery, subcostal incisions, and multiple rib fractures. Complications include pleural puncture, paravertebral hematoma, and nerve injury.[75] Paravertebral catheters are being placed more frequently in the PICU for patients with multiple rib fractures secondary to trauma as well as in patients who have undergone thoracotomy procedures. The use of this block in these patients can decrease the overall amount of sedation and analgesics used during mechanical ventilation and improve the patient's respiratory mechanics[82-84] (Fig. 130.2).

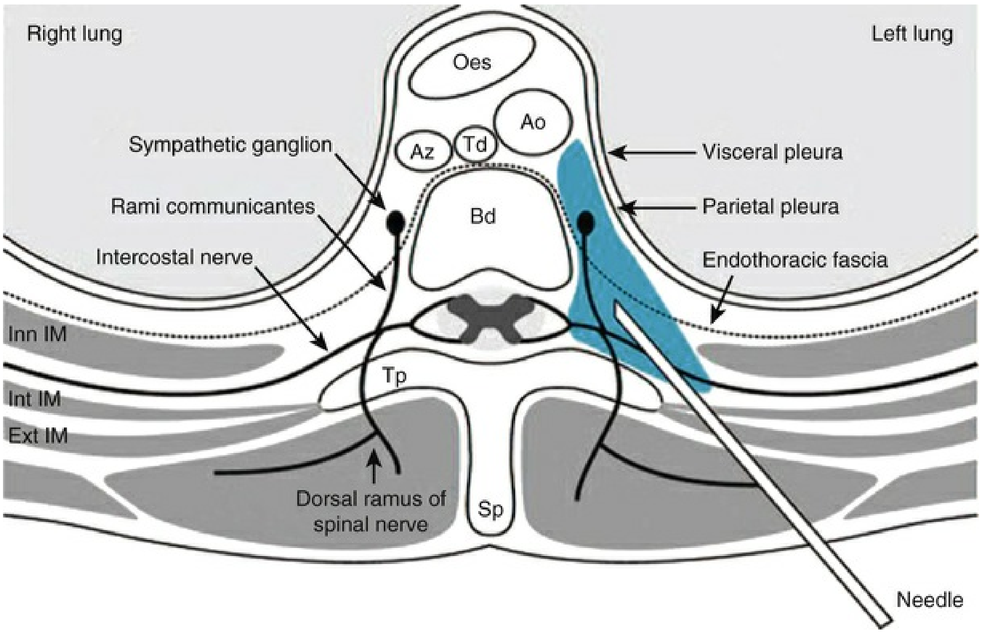

FIG. 130.2 Figure diagramming paravertebral space. The needle is advanced until the tip is in the paravertebral space. (From Cowie B, McGlade D, Ivanusic J, Barrington MJ. Ultrasound-guided thoracic paravertebral blockade: a cadaveric study. Anesth Analg. 2010;110:1735-1739.)

A transversus abdominis plane block with ultrasound guidance can improve the quality of abdominal wall blocks by directing the local anesthetic in the plane between the internal oblique and the transversus abdominis muscles where the thoracolumbar nerves lie. This block provides good postoperative analgesia and is indicated for laparoscopic procedures and for larger abdominal incisions[85,86] (Fig. 130.3).

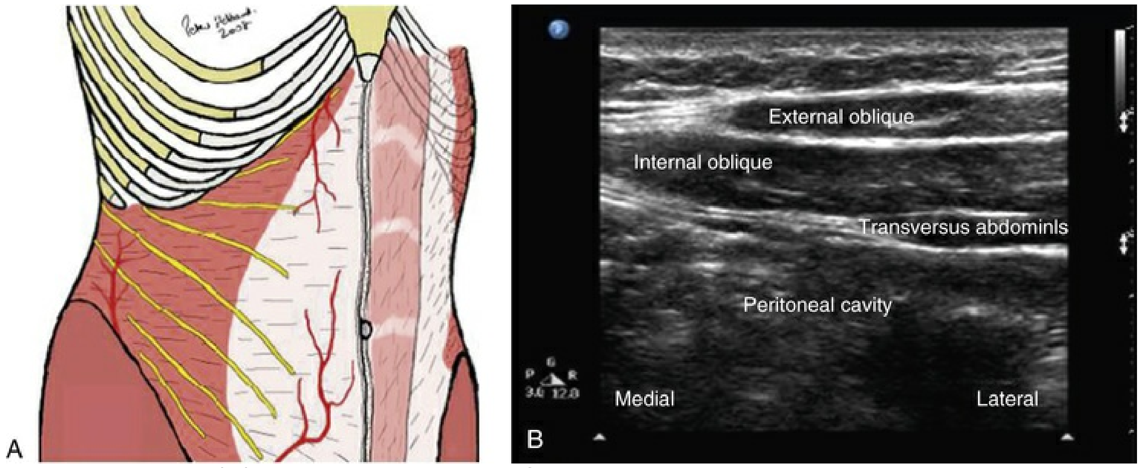

FIG. 130.3 (A) Typical distribution of nerves in the transversus abdominis plane block. (Generously shared from the personal files of Prof. P. Hebbard.) (B) Ultrasound view of abdominal wall lateral view. Muscular layers of the anterolateral abdominal wall.

Though anesthetic agents can affect the physiology of all organ systems, for the PICU patient the anesthetic effects on the patient's underlying CNS physiology can markedly influence a patient's outcome.

Neurologic Injury

Traumatic brain injury (TBI) is the leading form of pediatric trauma in the United States.[87,88] It is estimated that total combined rates of TBI-related hospitalizations, ED visits, and deaths are approximately 824 per 100,000.[89] Poor outcomes have been associated with early hypotension, low Glasgow Coma Scale score, altered cerebral blood flow (CBF), hyperglycemia, and deranged autoregulation.[90] However, secondary cerebral injury may result from the development of intracranial hypertension and resultant cerebral ischemia. Recognition and control of elevated intracranial pressure (ICP) are key elements to preventing neurologic deterioration and patient morbidity. Secondary traumatic brain injury can be characterized by an array of biochemical, cellular, and molecular events that are associated with ischemia, excitotoxicity, energy failure, and cell death cascades, all of which result in cerebral swelling, axonal injury, inflammation, and regeneration.[91]

Intracranial Pressure

The signs of intracranial hypertension in infants and children are listed in Table 130.1. The presence of these signs and symptoms, in conjunction with the baseline findings on neurologic examination, may dramatically alter the patient's anesthetic care. The anesthesiologist must be aware of ongoing interventions to control ICP. Control of cerebral perfusion pressure is essential for maintaining neurologic function in pathologic states. Cerebral perfusion pressure is expressed as the difference between MAP and the highest value obtained out of the following: central venous pressure, intrathoracic pressure, or ICP. Thus in the presence of intracranial hypertension (ICP ≥15 to 20 mm Hg), higher systemic blood pressures must be achieved to prevent cerebral ischemia. Intracranial compliance depends on the

volumes of the intracranial contents, cerebral tissue, blood, and extracellular fluid. The most dynamic of these is the blood compartment. Changes in cerebral blood volume are mediated primarily through changes in cerebral vascular resistance. Cerebral vascular resistance is affected by both intracranial and extracerebral factors.

TABLE 130.1

Signs of Intracranial Hypertension in Infants and Children

Infants	Children	Infants and Children
Irritability	Headache	Decreased consciousness
Full fontanelle	Diplopia	Cranial nerve (III and VI) palsies
Widely separated cranial sutures	Papilledema	Loss of upward gaze (setting sun sign)
Cranial enlargement	Vomiting	Signs of herniation, Cushing triad, pupillary changes

Regulation of Cerebral Blood Flow

The normal brain receives 15% of cardiac output. Kennedy and Sokoloff[92] determined that healthy children have a high CBF (100 mL/100 gm/min); this value decreases to adult values of 50 mL/100 gm/min during the teenage years. Cerebral blood flow regulation depends primarily on the local chemical and metabolic milieu, particularly the concentrations of hydrogen ion, adenosine, and prostanoids. Production of these compounds correlates with normal cerebral activity and metabolic rate. Neurogenic and myogenic components also have minor roles in regulating cerebral vascular resistance.

Extracerebral factors that can change cerebral vascular resistance and CBF include the arterial partial pressures of carbon dioxide ($Pa{CO_2}$) and oxygen ($Pa{O_2}$), MAP, and various drugs (Fig. 130.4). Cerebral circulation is sensitive to variations of $Pa{CO_2}$ and has been studied using transcranial Doppler ultrasound.[93] CBF varies linearly by 2% to 4% for every variation of 1 mm Hg of $Pa{CO_2}$. Data from anesthetized children show that CO_2 vasoreactivity is higher than in adults (13.8% versus 10.3% change).[94] Low blood pressure decreases cerebral vascular vasoreactivity.[94] As $Pa{CO_2}$ is rapidly lowered toward 20 mm Hg, there is marked cerebral vasoconstriction and a reduction in both CBF and ICP. Theoretically, an acute decrease in $Pa{CO_2}$ below 20 mm Hg may be detrimental by reducing CBF enough to cause cerebral ischemia. The salutary effects of acute hyperventilation on ICP are diminished over time because acute changes in cerebrospinal fluid pH are normalized in approximately 6 hours. Arterial oxygenation within the normal clinical range has little effect on cerebral vascular resistance. However, $Pa{O_2}$ less than 50 mm Hg results in cerebral vasodilation and increased CBF. Hyperoxia in excess of 300 mm Hg may produce cerebral vasoconstriction.

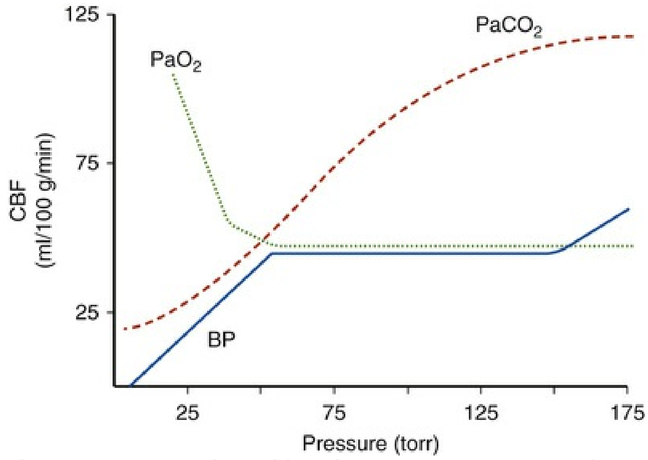

FIG. 130.4 Cerebral blood flow (CBF) changes resulting from alterations in $PaCO_2$, PaO_2, and blood pressure. The other two variables remain stable at normal values when the remaining variable is altered. (Modified from Shapiro HM. Intracranial hypertension: therapeutic and anesthetic considerations. Anesthesiology. 1975;43:445.)

Cerebral autoregulation is a homeostatic process by which the brain maintains a constant CBF over a MAP range from 60 to 150 mm Hg in adults. At a MAP less than 60 mm Hg, symptoms of cerebral ischemia may appear. If the upper limit of MAP for autoregulation is exceeded, the resultant increase in CBF may cause cerebral edema. The autoregulatory curve may shift in the presence of chronic hypertension, intracranial tumors, head trauma, or shock states. This renders the brain more susceptible to ischemic effects.[94] The range of MAP over which autoregulation of CBF occurs in infants and children likely shifts in tandem with age-related changes in normal systemic blood pressures and cerebral perfusion pressures. Raju and associates[95] suggested that an infant's mean cerebral perfusion pressure is approximately equal to its gestational age in weeks and that this estimate holds true for growing preterm infants up to 5 weeks after birth.

Effects of Anesthetics on Cerebral Blood Flow

In general, the potent inhaled anesthetic agents impair autoregulation and may cause hypotension and increased CBF (Fig. 130.5). Consequently, they must be used cautiously, if at all, in patients with evidence of traumatic brain injury. Halothane, historically at 1 MAC, abolishes cerebral autoregulation. Isoflurane impairs autoregulation less than halothane.[96] Sevoflurane appears to preserve autoregulation up to 1.5 MAC.[97-98] The effects of anesthetic agents on CBF and cerebral metabolism are summarized in Fig. 130.6. In general, the perfect agent would decrease both CBF and cerebral metabolic rate of oxygen ($CMRO_2$). The potent inhaled agents (isoflurane, desflurane, and sevoflurane) “uncouple” the normal relationship between CBF and metabolism and cause marked cerebral vasodilation. Isoflurane is the only inhaled anesthetic agent with which CBF actually may decrease when concomitant hyperventilation to $PaCO_2$ of 20 to 25 mm Hg is used.[99] Whereas nitrous oxide alone is known to cause mild cerebral vasodilation and to increase $CMRO_2$ (probably related to inadequate anesthetic depth), these effects are easily countered by the addition of intravenous sedatives, hypnotics, and narcotics. Sevoflurane has

been shown to increase CBF and ICP while decreasing $CMRO_2$.[100] The effects of desflurane on CBF have also been studied; Artru and colleagues[101] noted that desflurane increases CSF pressure in animals. Ornstein and colleagues[102] showed that in patients with intracranial mass lesions, desflurane and isoflurane have similar effects on CBF. The electroencephalographic effects of desflurane are similar to those of isoflurane, with prominent burst suppression occurring at 1.24 MAC.[103]

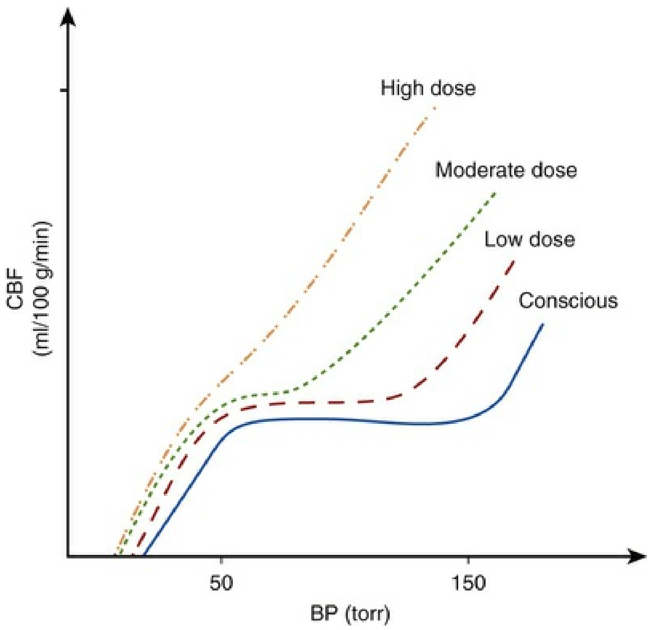

FIG. 130.5 Volatile anesthetics and autoregulation. Schematic representation of the effect of a progressively increased dose of a typical volatile anesthetic agent on cerebral blood flow (CBF) autoregulation. Both upper and lower thresholds are shifted to the left. (Modified from Drummond K, Shapiro HM. Cerebral physiology. In: Miller R, ed. Anesthesia. vol 2. 3rd ed. New York: Churchill Livingstone; 1990.)

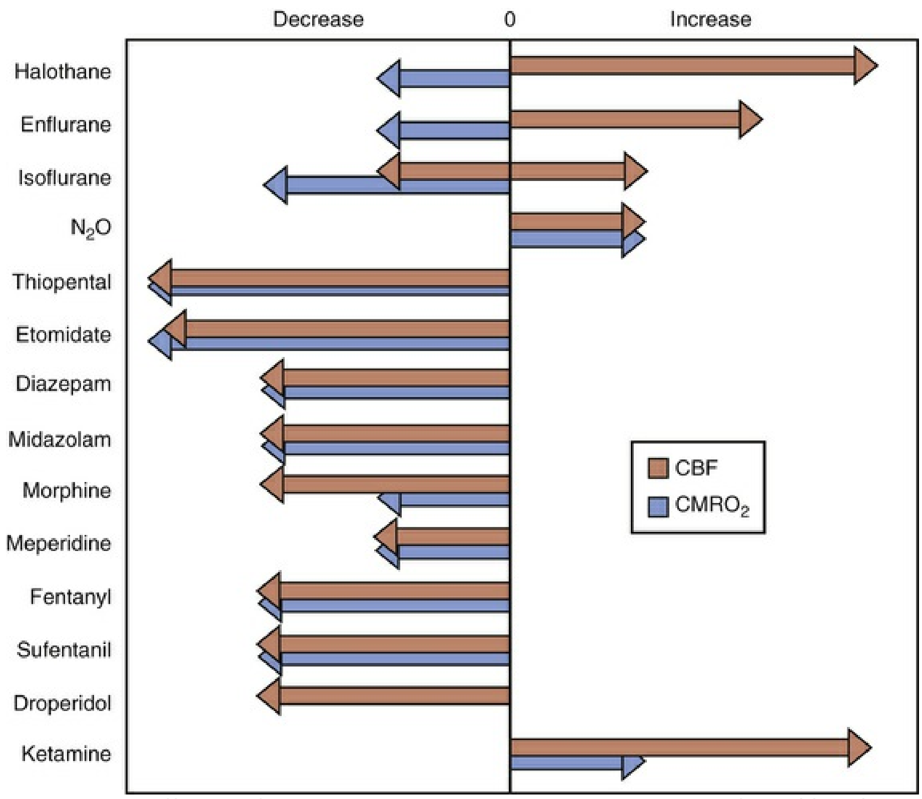

FIG. 130.6 Effects of anesthetic agents on cerebral blood flow (CBF) and cerebral metabolic rate of oxygen (CMRo2). (Modified from Cucchiara RF, Block MC, Steinkeler JA. The effects of anesthetic agents on cerebral blood flow and cerebral metabolism: anesthesia for intracranial procedures. In: Barash PG, Cullen BF, Stoelters SK, eds. Clinical Anesthesia. Philadelphia: JB Lippincott; 1989.)

In volunteers using transcranial Doppler, Bedforth and associates[104] noted that at 1 MAC of desflurane, cerebral autoregulation was impaired and that at 1.5 MAC autoregulation was abolished. In a separate study of adult non-neurosurgical patients, Bedforth and associates[104] noted that the introduction of desflurane following an induction of anesthesia with propofol impaired cerebral autoregulation more than with equi-MAC doses of sevoflurane. In contrast, in studies of static and dynamic compliance of autoregulation, Strebel and coworkers[105] noted that at 1.5 MAC desflurane and 1.5 MAC sevoflurane, autoregulation was impaired but propofol (200 μg/kg/min) had no effect. Muzzi and coworkers[106] showed that 1 MAC of desflurane in adults with supratentorial lesions increases ICP as opposed to 1 MAC of isoflurane. Desflurane may alter CSF dynamics. Desflurane does not appear to change CSF absorption but does increase CSF production.[107]

In a study of patients undergoing nonintracranial neurosurgical procedures, Summors and associates[107] noted that dynamic cerebral autoregulation using transcranial Doppler ultrasonography is better preserved during 1.5 MAC sevoflurane than during 1.5 MAC isoflurane anesthesia. Others noted similar findings with sevoflurane and isoflurane. In patients studied at 0.5 and 1.5 MAC, the dose-dependent vasodilatory effect was less for sevoflurane.[108,109] Nishiyama and coworkers[110] assessed comparative cerebral vasodilatory responsiveness to CO_2 during either sevoflurane or isoflurane anesthesia. They noted in a group of adult patients that changes in CBF caused by changes in CO_2 are greater during isoflurane

anesthesia. However, attempts to decrease ICP by decreasing CO_2 were more successful with isoflurane than with sevoflurane. In addition to cerebral vascular autoregulation, sevoflurane use is associated with epileptiform activity. In pediatric patients with and without a preexisting history of epilepsy, induction by sevoflurane of tonic, clonic, and silent seizures during the induction and maintenance of anesthesia has been reported.[109-113]

For the anesthesiologist, knowledge of the patient's ICP and cranial compliance and an understanding of the pathophysiology of the CNS lesion are important for planning appropriate anesthetic management.[114] In experimental animals, Statler and associates[114] demonstrated that isoflurane had more neuroprotective effect than fentanyl in rats that had undergone controlled cortical impact lesions. Hendrich and colleagues[115] quantified CBF using labeled magnetic resonance imaging in normal rats anesthetized with fentanyl, isoflurane, or pentobarbital. In this study, CBF values were found to be approximately 2.5 to 3 times lower in most regions analyzed during anesthesia with either fentanyl (with N_2O/O_2) or pentobarbital versus isoflurane (with N_2O/O_2). In addition, these investigators noted that CBF was heterogeneous in rats anesthetized with isoflurane (with N_2O/O_2) but relatively homogenous in rats anesthetized with either fentanyl (with N_2O/O_2) or pentobarbital. In previous human studies with opioid anesthesia, opioids maintained static cerebral autoregulation. Engelhard and associates[116] subsequently demonstrated that remifentanil, a μ-opioid agonist with unique pharmacokinetic properties, when combined with low-dose propofol maintains both static and dynamic compliance of cerebrovascular autoregulation. Propofol also has been used to alter CNS dynamics.[117] Positron emission tomography suggests that propofol produces global metabolic depression.[118,119] Like thiopental, propofol decreased $CMRO_2$, CBF, and ICP. Cerebral responsiveness to arterial CO_2 appears to be preserved during propofol anesthesia.[120-122]

Anesthesia Neurotoxicity in the Developing Brain

An area of intense interest in both the scientific community and lay press involves the findings of anesthetic-associated toxicity in the developing central nervous system.[1] Research in this area has focused on the neurodevelopment in the non–brain-injured and non–brain-diseased animal or patient. Early work in the 1980s by Uemura and colleagues noted that rats exposed to varying concentrations of halothane from the time of conception to PND28 had a decrease in synaptic density and that these exposed animals also demonstrated behavioral disturbances.[121,123] More recent investigations in both rodent and nonhuman primate models have reported apoptosis in multiple areas of the central nervous system during this period of rapid synaptogenesis when these animals are exposed to drugs that work via *N*-methyl-D-aspartate antagonists (NMDA) or gamma-aminobutyric acid (GABA) agonists.[124-133] Using caspase-3 as a marker for neuroapoptosis, investigators have reported both dose and length of exposure effects with ketamine, midazolam, propofol, sevoflurane, isoflurane, and desflurane in the developing brain (Fig. 130.7). When these agents are combined, these drugs act synergistically with regard to both

their anesthetic action and their neuroapoptotic effect. In addition to a dose effect, these animals have a period, or window of vulnerability, in which these agents act in the developing brain. This window of vulnerability differs among species, and though there are no specific studies on the vulnerability period in humans, these animal models suggest that the vulnerable period in humans correlates to a human period of late pregnancy to early childhood. Although the data are mixed with respect to the behavioral/neurocognitive outcomes in rodents, the little data available in primates suggest neurocognitive impairment in older animals that were exposed to ketamine in the neonatal period.[134]

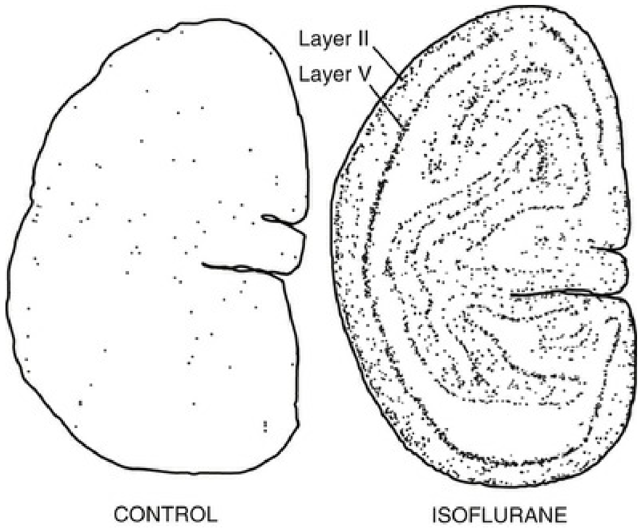

FIG. 130.7 Computer plots based on the number and location of each activated caspase-3–stained neuronal profile in homologous sections from the primary visual cortex of a control and isoflurane brain. Note the laminar pattern of distribution of stained neuronal profiles in the isoflurane brain and the randomly scattered pattern in the control brain. The layers primarily affected in the isoflurane brain are layers II and V. (From Brambrink AM, Evers AS, Avidan MS, et al. Isoflurane-induced neuroapoptosis in the neonatal rhesus macaque brain. Anesthesiology. 2010;112:834-841.)

To complicate the situation, rodent studies have shown that ketamine exposure during this period of rapid synaptogenesis can increase neuroapoptosis and alter behavior in exposed rat pups; however, if rat pups are exposed to chronic pain (in the absence of the drug), chronic pain can also cause an increase in neuroapoptosis. If these animals are exposed to chronic pain and ketamine, neuroapoptosis is markedly attenuated.[135] Stratmann and colleagues have shown in rat pups that exposure to increased levels of carbon dioxide results in an increase in neuroapoptosis to a level that is similar to that observed with exposure to isoflurane. However, neurocognitive performance in the carbon dioxide exposed group was similar to control animals, whereas animals exposed to isoflurane had neurocognitive impairment.[129] Stratman and coworkers challenged the view of neuroapoptosis and have suggested that anesthetic agents may affect neurogenesis.

Anesthetic neurotoxicity animal investigations have also focused on dendritic synaptic density in neonatal animals exposed to anesthetic agents. De Roo and colleagues, using a rodent model, demonstrated the age-related effects of propofol

on dendritic spine density. Exposure of rat pups to propofol at postnatal days 5 and 10 significantly decreased dendritic spine density, whereas on postnatal days 15, 20, or 30 propofol exposure increased dendritic spine density. In addition, the propofol-induced modifications in dendritic spine densities persisted up to postnatal day 90. Exactly how these developmental changes affect neural circuit connectivity and neurocognitive function is unclear.[136]

Other animal studies have correlated biomarkers of inflammation with neurotoxicity. In studies of pregnant mice (gestational day 14) and mouse primary neurons exposed to sevoflurane, sevoflurane increased caspase-3 activation, increased interleukin-6, decreased postsynaptic density-95, and decreased synaptophysin levels in the brains of both the fetal and the offspring mice. In addition, in separate learning and memory tests (Morris water maze), sevoflurane anesthesia impaired learning and memory in offspring mice when tested at P31. Of equal importance was that if the sevoflurane-exposed animals were placed in an enriched environment, the biomarker changes were attenuated and the animal's learning and memory performance were similar to that of the control animals.[137]

How these findings in animals translate to humans is less clear. Some studies suggest a possible association of anesthesia exposure with neurocognitive impairment, whereas others do not. Wilder and others, looking at databases and county registries in the Rochester, Minnesota, area, suggest that exposure to anesthesia may have a detrimental effect with regard to learning disabilities. In this study, the investigators reported on a cohort of 5357 births in Rochester, Minnesota, between 1976 and 1982. The incidence of learning disabilities and its relationship to anesthetic exposure was determined while adjusting for other possibly relevant covariables.[138] In this study, the authors concluded that two or more anesthetic exposures before the age of 4 years increased the odds of a learning disability (Fig. 130.8). Another study to suggest an association between anesthetic exposure and neurobehavioral outcome is the report of Ing and associates, who performed an analysis of the Western Australian Pregnancy Cohort (Raine) Study, which included children born from 1989 to 1992. In this cohort, 321 children were exposed to anesthesia before age 3 and 2608 were not. The anesthetized group of children had a higher relative risk of language and abstract reasoning deficits when studied at age 10 than children who had not received an anesthetic before age 3.[139]

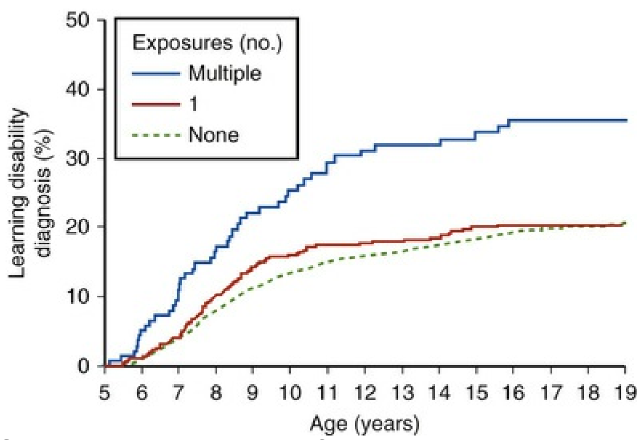

FIG. 130.8 Cumulative percentage of learning disabilities diagnosis by the age of exposure shown separately for those who have zero, one, or

multiple anesthetic exposures under the age of 4. (From Wilder RT, et al. Early exposure to anesthesia and learning disabilities in a population-based birth cohort. Anesthesiology. 2009;110:796-804.)

However, in a study of twin cohorts from the Netherlands, Bartels and others reported no causal relationship between anesthesia and learning deficits. In their study of 1143 monozygotic twin pairs, Bartels and colleagues noted that twins exposed to anesthesia before age 3 had significantly more cognitive problems and lower educational achievement scores than did twins not exposed to anesthesia. However, in twin pairs that were discordant for anesthesia (ie, one twin exposed and one twin not exposed), these twins were not different from each other.[140]

At the moment with the exception of xenon and dexmedetomidine, most anesthetic agents and adjuncts have been associated with neurotoxicity in experimental animal models. Both xenon and dexmedetomidine have been shown to attenuate the neurotoxic effects of ketamine, isoflurane, sevoflurane, and propofol.[141-143] Large-scale clinical studies to better define the role of anesthesia and the inflammatory response to surgery will be needed to determine the role of neurotoxicity for anesthetic agents as well as define a biomarker or phenotype for the patient truly at risk from these agents.

CHAPTER 131

Anesthesia Principles and Operating Room Anesthesia Regimens

Joseph D. Tobias

PEARLS

- The preoperative evaluation includes a history of present illness, past medical problems including medication allergies, a past surgical and anesthetic history, a family history of anesthetic complications, and a review of the patient's current and possibly prior medical record including the medication list.
- In its simplest form, a general anesthesia includes amnesia, analgesia, muscle relaxation, and attenuation of the sympathetic nervous system's response to surgical trauma. The phases of general anesthesia include induction, maintenance, and emergence.
- The standards for intraoperative anesthetic monitoring have been outlined by the American Society of Anesthesiologists and include an oxygen analyzer, noninvasive blood pressure cuff, continuous electrocardiogram, pulse oximeter, end-tidal carbon dioxide analyzer, precordial or esophageal stethoscope, temperature probe, and ventilator disconnect alarm.
- Given the catastrophic effects of local anesthetic toxicity, mechanisms to avoid it and prevent its occurrence are mandatory during the performance of regional anesthetic techniques in infants and children. Epinephrine (0.5 μg/ml) is added to the local anesthetic solution during performance of a regional anesthetic technique to serve as a marker of inadvertent systemic injection.
- Following the successful completion of the surgical procedure, a plan is determined for the postoperative delivery of analgesia including some combination of intravenous opioids, agents to inhibit prostaglandin formation or a regional anesthetic technique. For major surgical procedures, the most effective way to deliver opioids for postoperative analgesia is patient-controlled analgesia.

Introduction

Intraoperative surgical anesthesia can be provided by several different techniques, which generally include the following:

1. Local anesthesia ("local only"): This involves the infiltration of a surgical site with a local anesthetic agent to render the site insensitive to pain. This may be done solely by the surgeon without the involvement of an anesthesia provider.

2. Monitored anesthesia care (MAC): MAC is generally equivalent to procedural sedation and involves monitoring a patient with standard monitors according to the American Society of Anesthesiologists (ASA monitors, discussed later) while administering a sedative or analgesic agent intravenously to provide anxiolysis, sedation, and analgesia. MAC is frequently combined with either infiltration of the surgical site with a local anesthetic agent or a regional anesthetic technique. In general, it includes a combination of a medication with amnestic properties (midazolam or propofol) combined with a medication to provide analgesia such as opioid (fentanyl). During MAC, spontaneous ventilation with a native airway is maintained, thereby eliminating the need for endotracheal intubation and controlled ventilation. The depth of sedation may range from a state in which the patient is awake and relaxed with the ability to respond to verbal stimuli to a state of deep sedation where a painful stimulus is required to elicit a response.

3. Peripheral nerve blockade and neuraxial anesthesia: The techniques are frequently considered together under the title of regional anesthesia. A peripheral nerve block involves the placement of a local anesthetic agent around a nerve or group of nerves (plexus) to render specific dermatomes insensitive to pain. Examples of plexus blockade include cervical plexus blockade for superficial and deep neck surgery, brachial plexus blockade for upper extremity or shoulder procedures, and lumbar plexus blockade for hip or leg surgery.[1-3] Intravenous regional anesthesia, the Bier block, is another example of a peripheral nerve block that can be used to provide surgical anesthesia. A Bier block involves the intravenous injection of a dilute local anesthetic into a vein of an extremity after that extremity has been exsanguinated by wrapping it with a bandage followed by occlusion with a tourniquet. Although the latter technique is generally successful and easy to accomplish, it may not be feasible in younger children except when combined with deep sedation. Given the use of an occlusive tourniquet, its duration is limited to 60 to 70 minutes due to tourniquet pain. The major concern with the Bier block is that the dose of local anesthetic used approaches the toxic limits and should the tourniquet fail, cardiovascular or central nervous system (CNS) consequences from the local anesthetic agent may occur. Neuraxial anesthesia involves the injection of a local anesthetic agent into either the subarachnoid or epidural space. This results in blockade of the spinal cord and its accompanying nerve roots to render an entire region of the body (lower abdomen, pelvis, perineum, or lower extremities) insensitive to pain. Examples of neuraxial anesthesia include spinal, epidural, and caudal anesthesia.[4,5] In infants and children, a regional anesthetic technique such as a peripheral nerve block or epidural anesthesia can be used instead of general anesthesia in patients with comorbid diseases, which significantly increase the risk of anesthesia. More frequently, the regional anesthetic technique is combined with a general anesthetic as part of a

balanced anesthetic technique and continued into the postoperative period by use of a continuous infusion via the catheter to provide postoperative analgesia.

4. General anesthesia: General anesthesia is the most frequently used intraoperative technique in the pediatric population. When general anesthesia is used, it usually includes the administration of medications to provide the requisites of amnesia, analgesia, muscle relaxation, and attenuation of the sympathetic nervous system's response to surgical trauma.

The phases of general anesthesia include induction, maintenance, and emergence. The induction of anesthesia can be carried out with the intravenous administration of an intravenous anesthetic agent (thiopental, propofol, ketamine, or etomidate) or via the inhalation route with an inhalational (volatile) anesthetic agent such as sevoflurane. Advantages of an intravenous induction include the rapid onset of anesthesia and avoidance of issues associated with inhalation induction including claustrophobia from anesthesia mask placement and the odor of the inhalational anesthetic agent. In pediatric patients, the inhalation induction of anesthesia is frequently chosen to avoid the need for obtaining intravenous access on an awake child. When inhalation induction is carried out without intravenous access, airway and cardiovascular issues may arise and mandate immediate treatment without intravenous access. In such cases, if intravenous access cannot be rapidly obtained, it may be feasible to use the intramuscular (IM) route for a select number of medications (atropine, succinylcholine). However, more aggressive resuscitation such as the administration of epinephrine for hemodynamic compromise may require the use of intraosseous access (IO).[6] Fortunately, the majority of problems during inhalation induction can be easily reversed with appropriate airway techniques or the administration of IM medications. Hemodynamic compromise including cardiac arrest was far more common with the use of halothane given its negative inotropic and chronotropic properties.[7] Given these and other concerns, halothane is no longer used in the practice of anesthesia, having been replaced by sevoflurane. Even if intravenous access is present, the inhalational induction of anesthesia may be chosen, as it allows the maintenance of spontaneous ventilation even during deep planes of anesthesia (deep enough to allow for direct laryngoscopy and endotracheal intubation). Such a technique may be used if there is a question regarding the ability to bag-valve-mask ventilate the patient, such as may occur in patients with a potentially compromised airway from infection, tumor, congenital or anatomic abnormalities. Following anesthetic induction, one progresses into the maintenance phase of general anesthesia. This can by provided by the administration of intravenous agents, inhalational agents, or, often, a combination of the two. An example of a balanced technique includes some combination of inhalational agents (nitrous oxide and a volatile anesthetic agent), a continuous infusion of an intravenous anesthetic (propofol), a nondepolarizing neuromuscular blocking agent (NMBA), and an opioid. In most circumstances, the choice of maintenance anesthesia is based on the presence of comorbid features, the type of surgical procedure, and the preferences of the anesthesiologists.

Preoperative Evaluation

Regardless of the type of procedure, the patient's status, and the planned anesthetic technique, a preoperative evaluation is performed at some point prior to anesthetic care. In many centers, this evaluation is performed well in advance of the anticipated surgical procedure in a specialized clinic to allow for specific preoperative interventions, consultation, or preparation that may be required to allow for the safe completion of the anesthetic care and surgical procedure. Alternatively, in low-risk patients without accompanying comorbid diseases, the preoperative evaluation can be performed on the phone using a standardized survey or in person the day of surgery. For patients who are already admitted to the hospital or those presenting for emergent or urgent surgical procedures, the preoperative evaluation is also generally done just prior to the surgical procedure.

The preoperative evaluation includes a history of present illness, past medical problems including medication allergies, a past surgical and anesthetic history, a family history of anesthetic complications, and a review of the patient's current and possibly prior medical record including the medication list. For elective surgical procedures, the status of comorbid conditions should be optimized prior to the surgical procedure. The latter may not be feasible for urgent or emergent cases. The physical examination is directed primarily at the central nervous system, cardiovascular system, and respiratory system including an examination of the airway. The preoperative evaluation attempts to identify patients with a difficult airway, which may preclude successful endotracheal intubation using standard techniques of direct larygnoscopy.[8] As a full description of the airway examination is beyond the scope of this chapter, the reader is referred to reference 8 for additional details. An airway history should be obtained seeking medical, surgical, and anesthetic factors that may indicate a difficult airway. Examination of previous anesthesia records is helpful, although a patient's airway may change with changes in weight, with aging, or with the development of comorbid conditions. A physical examination of the airway is performed to detect physical characteristics associated with a difficult airway such as a large tongue, small mouth, short neck (shortened thyromental distance), recessed mandible (micrognathia), limited extension or flexion of the neck, and limited mouth opening. The patient is then asked to open his or her mouth so that the uvula and tonsillar pillars can be assessed. The view of the oropharynx is assessed using the Mallampati grading system. Visualization of the entire uvula and tonsillar pillars (Mallampati grade 1) suggests that endotracheal intubation will be uncomplicated, whereas failure to visualize the tonsillar pillars and the soft palate (Mallampati class IV) suggests that endotracheal intubation will be difficult. Based on the preoperative evaluation and the identification of comorbid conditions, an ASA Physical Status classification is assigned (Table 131.1). The physical classification is based on the physical condition of the patient and does not include the planned surgical procedure. Laboratory tests and additional investigations are ordered based on the positive findings obtained during the history and physical examination and on the complexity of the surgical procedure.[9] The routine preoperative testing of all patients for elective surgery has been shown to be unjustified and expensive. In the absence of comorbid conditions, for surgical procedures with limited chance of significant blood loss, no laboratory or radiologic evaluation is necessary. Although commonly performed, routine testing of coagulation function has been shown to be of limited value without an antecedent history of bleeding problems.[10] The most common coagulation disorder that may

cause problems intraoperatively is von Willebrand disease, which cannot be identified on routine coagulation screening that includes a prothrombin time (PT), partial thromboplastin time (PTT), and an international normalized ratio (INR). In patients presenting for surgical procedures that may require the administration of allogeneic blood products, a hemoglobin is assessed and a type and screen obtained. In specific clinical scenarios, especially in the pediatric population, in whom awake phlebotomy may be problematic, these may be obtained and sent immediately following the induction of anesthesia and placement of an intravenous cannula.

TABLE 131.1

American Society of Anesthesiologists Physical Status Classification

Classification	Description	Example
1	Normal healthy patient	—
2	Mild systemic disease with no functional limitation	Mild asthma, acyanotic congenital heart disease (atrial septal defect)
3	Severe systemic disease with functional limitation	Sickle cell disease, cystic fibrosis, palliated cyanotic congenital heart disease
4	Severe systemic disease that is a constant threat to life	Advanced stages of muscular dystrophy, cyanotic congenital heart disease with pulmonary hypertension
5	Moribund patient not expected to survive without operation	Perforated bowel with sepsis and shock
6	Brain-dead patient; organs are being removed for donor purposes	—
E	Emergency operation	—

Another area of ongoing controversy is the need for routine preoperative pregnancy testing in postmenarchal patients. Given the theoretic potential for anesthetic agents to be teratogenic and to increase the risk of spontaneous abortion, the history should include specific questioning about the potential for pregnancy including the patient's last menstrual cycle. There is increasing use of a point-of-care urine pregnancy testing in many centers. Further testing such as pulmonary function tests, electrocardiography, and echocardiography are based solely on the presence of comorbid conditions. Following the preoperative visit including the history and physical examination, the planned management of anesthesia is discussed with each patient. Risks and possible complications are reviewed. Options and plans for postoperative pain management are discussed. The answering of questions and obtaining an informed consent complete the preoperative evaluation.

NPO Guidelines

Although the aspiration of gastric contents is an uncommon event, the consequences may be severe and include pneumonitis, respiratory failure, or even death. Classical teaching states that the severity of the aspiration injury relates to the volume aspirated as well as its pH with severe complications when aspiration includes a volume ≥0.4 mL/kg or a pH ≤2.5. Although aspiration may occur in any setting, patients at risk include parturients, obese patients, diabetics, patients who have received opioids, patients with gastrointestinal disease (reflux, obstruction), patients with altered mental status, patients with intraabdominal pathology (acute abdominal emergencies including appendicitis), trauma patients, and those in whom difficult airway management is anticipated. Specific comorbid conditions may predispose to aspiration by limiting the patient's ability to protect his or her own

airway, decreasing the normal barrier to aspiration (lower esophageal sphincter tone), increasing gastric volume, or delaying gastric emptying.[11,12] Patients who have the highest incidence of perioperative aspiration are those with a high ASA physical status classification (III, IV, or V) and those having emergency surgery. The majority of aspirations occur during the induction of anesthesia or following tracheal extubation when the patient has lost his or her protective airway reflexes.

Keeping patients *nil per os* (NPO) remains the mainstay of therapy to prevent acid aspiration. In the past, patients were fasted for 8 to 12 hours before surgery to reduce the volume of gastric contents at the time of induction of anesthesia and to decrease the risk of aspiration pneumonitis. This preoperative fast does not take into account differences in gastric emptying of clear liquids and solids. Based on several investigations and clinical experience, there has been a significant revision in the perioperative fasting rules especially for infants and children. It has been demonstrated that clear liquids have a gastric emptying time of 1 to 2 hours, whereas solids have an unpredictable gastric emptying time that may be greater than 6 hours.[13-16] The ingestion of clear liquids up to 2 hours before surgery does not increase gastric fluid volume or acidity.[13-16] As a result, the liberalization of guidelines for ingestion of clear liquids for elective surgery of otherwise healthy patients has been recommended.[17-19] Suggested guidelines as recommended by the American Society of Anesthesiologists for patients with no known risk factors include no solid food for at least 6 hours before surgery and unrestricted clear liquids until 2 hours before surgery. Importantly, instead of merely allowing clear liquids prior to surgery, their administration is encouraged and parents are reminded to allow their children to have clear liquids (apple juice) prior to coming to the hospital. This improves hydration and limits irritability related to NPO time. Oral medications should be given 1 to 2 hours before surgery with a small sip of water. The latter is particularly important for specific medications such as anticonvulsants, and postoperative seizures may occur related to missing a single preoperative dose.[20] Although, on theoretic grounds, several maneuvers may be indicated in patients with risk factors for acid aspiration, there is limited if any evidence-based medicine to demonstrate their efficacy in preventing perioperative aspiration. Many centers routinely use preoperative medications to decrease the acidity of the gastric fluid (H_2 antagonists or proton pump inhibitors) and speed gastric emptying (metoclopramide). To be effective, it is recommended that these medications be administered 60 to 90 minutes prior to anesthetic induction. Alternatively, a nonparticulate antacid (sodium bicitrate) can be given immediately prior to anesthetic induction, a common practice in obstetrical anesthesia. However, not one of these practices has been shown to alter outcome when examined rigorously using evidence-based medicine.[21] In patients at risk for acid aspiration, rapid sequence induction (RSI) is commonly practiced. This involves the use of a rapidly acting neuromuscular blocking agent (discussed later) with an anesthetic induction agent and the application of cricoid pressure. As the cricoid is the only complete ring of the trachea, it can be gently pushed posteriorly to effectively occlude the esophagus and prevent passive regurgitation of gastric contents when consciousness is lost during anesthetic induction. In its classical form, RSI involves preoxygenation, the administration of an anesthetic agent (sedative) and NMBA in rapid sequence, and the performance of endotracheal intubation without bag-valve-mask ventilation. Bag-valve-mask ventilation is not provided, as it may distend the

stomach and predispose to regurgitation. Without assisted ventilation, oxygen desaturation may occur in infants and small children, patients with reduced functional residual capacity, or those with significant alveolar space disease. Additionally, as the anesthetic agent (sedative) and NMBA are administered in rapid sequence without demonstrating the ability to provide bag-valve-mask ventilation, this may result in a “cannot intubate–cannot ventilate” scenario. A modification of this technique, known as a modified RSI, uses gentle bag-valve-mask ventilation with a peak inflating pressure less than 20 cm H_2O to provide oxygenation and ventilation while waiting for the anesthetic agent and NMBA to take effect. The modified RSI may be used more commonly in pediatric anesthesia as even brief periods of apnea without bag-valve-mask ventilation may result in precipitous decreases in oxygenation due to the low functional residual capacity and high metabolic rate for oxygen in young children and infants. Although RSI is commonly practiced, it is not universally accepted and has not been tested using evidence-based medicine.[22] It has been demonstrated that even in experienced hands, especially in young infants and children, the correct application of cricoid pressure is problematic.[23]

Preoperative Medication

There are several categories and uses of preoperative medications (Table 131.2). The most common use of a preoperative medication is to provide sedation and anxiolysis prior to transport to the operating room. Preparing the patient for surgery includes psychologic preparation and frequently pharmacologic premedication. Psychologic preparation includes the preoperative visit and an interview by the anesthesiologist. Pharmacologic premedication may be given orally, or rarely intramuscularly, 1 to 2 hours before the induction of anesthesia or intravenously in the immediate preoperative period. Popular choices include benzodiazepines such as midazolam or occasionally α_2-adrenergic agonists such as clonidine or dexmedetomidine. A frequently used agent and route of administration for the pediatric patient is the oral administration of the benzodiazepine midazolam to ease separation from parents and improve mask acceptance for the inhalation induction of anesthesia. This is generally necessary when children are at least 9 to 18 months of age and begin to manifest stranger anxiety. Given alterations in bioavailability when administered by the oral route, doses of 0.3 to 0.5 mg/kg are required.[24]

TABLE 131.2

Types and Uses of Premedications

Type of Medication	Purpose
Benzodiazepine	Sedation, anxiolysis, amnesia—eases parental separation
Alpha$_2$-adrenergic agonists (clonidine, dexmedetomidine)	Sedation, anxiolysis—decrease intraoperative anesthetic needs
Opioids	Analgesia during invasive procedures
Anticholinergic agents (atropine, glycopyrrolate)	Prevent bradycardia, blunt airway reflexes, dry secretions
Inhaled β-adrenergic agonists (albuterol) and anticholinergic agents (ipratropium)	Prevent or relieve bronchospasm
Inhaled lidocaine	Prevent airway reflexes during awake fiberoptic intubation, direct laryngoscopy, or bronchoscopy
H_2 antagonists, proton pump inhibitors	Decrease pH of stomach contents

Promotility agents such as metoclopramide	Decrease volume of gastric secretions
Antiemetic agents (scopolamine patch, neurokinin-1 inhibitors)	Prevent perioperative nausea and vomiting

Additional preoperative medications may be used in patients with certain comorbid features including the use of H_2 antagonists, proton pump inhibitors, or motility agents to increase gastric pH and decrease gastric volume in patients at risk for acid aspiration, whereas inhaled β-adrenergic agonists (albuterol) or anticholinergic agents (ipratropium) may be administered to patients with reactive airway diseases (asthma, recent upper respiratory infection, or chronic obstructive pulmonary diseases). Anticholinergic agents may be used to dry airway secretions in patients requiring fiberoptic intubation.

Monitoring

The American Society of Anesthesiologists has outlined the standards for intraoperative anesthetic monitoring. The monitoring standards are the same regardless of whether the case entails a general anesthetic, regional anesthetic (peripheral nerve block, spinal, or epidural), or monitored anesthesia care. The standards according to the ASA include an oxygen analyzer, noninvasive blood pressure cuff, continuous electrocardiogram (ECG), pulse oximeter, end-tidal carbon dioxide analyzer, precordial or esophageal stethoscope, temperature probe, and a ventilator disconnect alarm.

Although arrhythmias are generally uncommon, bradycardia may occur due to the administration of the volatile anesthetic agents (halothane or sevoflurane), hypoxemia, hypothermia, alterations in intracranial pressure, or from the oculocardiac or trigeminocardiac reflex. Although generally devoid of significant negative chronotropic properties, profound bradycardia may occur with the administration of sevoflurane to patients with trisomy 21.[25] In most clinical scenarios, a three-lead ECG is used with the demonstration of lead II to facilitate the identification of P wave morphology and arrhythmia analysis. In adult patients and in specific pediatric patients, a five-lead ECG is used to facilitate ischemia detection along the anterior myocardium. Other potential applications for intraoperative ECG monitoring include identification of potentially lethal electrolyte disturbances such as hyperkalemia, rare instances of prolonged QT syndrome (congenital, acquired, or drug-induced), and monitoring for inadvertent systemic injection of local anesthetic agents.[26] By using the T-wave, systolic blood pressure (BP), and heart rare (HR) criteria, the positive response rate to an epinephrine test (0.1 mL/kg of a 1 : 200,000 solution or 0.5 μg/kg) was 100%, 95%, and 71%, respectively, during sevoflurane anesthesia and 90%, 71%, and 71% during halothane anesthesia.[27,28]

Pulse oximetry estimates the saturation percentage of the hemoglobin. It is not meant as a surrogate measure of the partial pressure of oxygen in the blood (PaO_2), especially at its extreme values. The relationship between PaO_2 and oxygen saturation is affected by many factors including the type of hemoglobin and the state of the oxyhemoglobin dissociation curve. The latter is affected by acid-base status, temperature, and 2,3-diphosphoglycerate (DPG) levels. Pulse oximetry is known to be inaccurate during periods of hypoxemia (saturation less than 85%–90%) and generally reads 98% to 100% when the PaO_2 exceeds 100 mm Hg. Both patient-

related and external factors may interfere with its accuracy including motion and low tissue perfusion. New technology has led to the introduction of low-perfusion pulse oximetry that provides accurate readings during low perfusion states, devices using six to eight wavelengths of light instead of two that can identify abnormal hemoglobin species (carboxyhemoglobin, methemoglobin), improved accuracy at saturation levels less than 90%, and alternative sites for monitoring such as the forehead, which may not be affected by low perfusion states.

End-tidal carbon dioxide ($ETCO_2$) monitoring or capnography remains a standard of care for intraoperative monitoring. It not only documents the initial correct placement of the endotracheal tube, but it ensures ongoing ventilation during the case. $ETCO_2$ displays the patient's exhaled carbon dioxide concentration continuously during exhalation with the $ETCO_2$ being the peak value before the next breath is initiated. When used continuously in the operating room setting, the technology provides a continuous estimation of the partial pressure of CO_2 ($PaCO_2$) in the blood as well as serving as a disconnect alarm during mechanical ventilation, monitoring respiratory rate, and providing information regarding pulmonary function via the shape of the capnogram. Abrupt changes in the $ETCO_2$ such as decreases related to increased dead space may alert the clinician to decreased cardiac output or alterations in pulmonary perfusion related to gas or pulmonary embolism. Acute increases in $ETCO_2$ may be the initial sign of malignant hyperthermia or other hypermetabolic states.

The normal capnogram has three phases of exhalation and one of inspiration, generally labeled as phases 1 through 4. Phase 1 is the beginning of exhalation, representing dead space ventilation and therefore having no $ETCO_2$ present. If $ETCO_2$ is present during phase 1, this indicates the rebreathing of exhaled gas, which may be due to inadequate fresh gas flows. Phase 2 is the rapid and steep upslope of the capnogram representing the emptying of alveolar gas with dead space gas. Phase 3 is the plateau phase, which in the normal state should be relatively horizontal. Upsloping of phase 3 of the capnogram is indicative of obstructive lung disease (asthma, bronchospasm) with differential emptying of alveoli with varying time constants. With the initiation of inspiration, there is an abrupt decrease of the $ETCO_2$ (phase 4), which should return to 0 mm Hg. The $ETCO_2$ generally correlates in a clinically useful fashion with the $PaCO_2$ with the $ETCO_2$ being 2 to 4 mm Hg lower than the $PaCO_2$ and can be used to adjust intraoperative ventilation. However, this correlation is dependent on effective matching of ventilation with perfusion. The relationship between the $ETCO_2$ and $PaCO_2$ may be affected by technology and patient-related factors. Such issues may be particularly relevant in the practice of pediatric anesthesia where smaller tidal volumes, type of ventilation (continuous versus intermittent flow), and sampling issues may have an effect. With these caveats in mind, its use has expanded outside of the operating room with its addition to the suggested monitoring guidelines for procedural sedation from the American Society of Anesthesiologists, which are used to judge the adequacy of resuscitation and to prevent inadvertant hyperventilation during patient transport.[29,30]

Based on the medical condition of the patient and the surgical procedure, more elaborate, invasive monitoring may be added to these standard monitors such as a

urinary catheter, catheters for measuring intraarterial, central venous, pulmonary artery pressures, and transesophageal echocardiography. Although there are no strict guidelines dictating which patients should have invasive monitors placed, there have been recommendations set forth for the adult population. It must be remembered, however, that these recommendations are based on limited data comparing outcomes in patients managed perioperatively with or without pulmonary artery (PA) catheters.[31,32] The ASA recommends considering three variables, including disease severity, magnitude of the surgical procedure, and practice setting when assessing the benefit versus risk of PA catheters.[33,34] Additional information regarding structural and functional issues of the myocardium may be obtained by the use of transesophageal echocardiography (TEE). TEE is being used more frequently in the adult population with the development of specific curriculum to teach the skills necessary to perform TEE during cardiac anesthesia fellowships. The latter has been followed by the American Board of Anesthesiology, which recognizes such training and provides the opportunity for credentialing through the completion of a written examination. The strongest indications for perioperative transesophageal echocardiography that are supported by evidence-based medicine include cardiac surgery procedures such as repair of valvular lesions (insufficiency or stenosis) or congenital lesions, assessments and repairs of thoracic aortic aneurysms and dissections, pericardial window procedures, and the repair of hypertrophic obstructive cardiomyopathy.[34] For noncardiac surgery, intraoperative transesophageal echocardiography may be indicated to evaluate acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment especially when placement of a PA catheter is not feasible.

Given the current limitations of the clinical available measures of cardiac output (TEE or PA catheter), there is ongoing interest in the development of accurate and noninvasive means of assessing cardiac output. Doppler-based techniques, specifically transesophageal Doppler, provide a noninvasive alternative with accuracy that is similar to, though not superior to, thermodilution. Calibrated pulse contour analysis is superior to uncalibrated pulse contour analysis, though both tend to suffer during periods of hemodynamic instability. Bioreactance is completely noninvasive and shows promising accuracy in comparison to thermodilution. It is, however, a relatively new technology when compared to its thermodilution and Doppler counterparts. More research is needed before meaningful conclusions can be made regarding the clinical utility of bioreactance, whereas bioimpedance monitors have shown poor accuracy and cannot be recommended for clinical use. At this point, none of these technologies can be considered the standard of care, and in most circumstances, their use is confined to clinical investigations with limited applications in standard operating room patient management.

In addition to the standard ASA monitors and other monitors of hemodynamic function previously discussed, there is growing interest in the development and potential use of *depth of anesthesia* monitors to allow titration of anesthetic agents (inhaled and intravenous). Although these monitors may have several potential benefits, their primary role has been to possibly decrease the incidence of intraoperative awareness. Although controversial, the potential impact of such monitors is highlighted by the results of trials, which demonstrate that intraoperative awareness occurs in approximately 0.1% to 0.2% of all patients.

Specific patient populations are at higher risk, including those affected by trauma, cardiac, obstetric, and emergency surgery. Several manufacturers have marketed or are developing monitors that provide the anesthesia provider with a numeric value against which anesthetic agents are titrated. The most commonly used monitors include the Bispectral Index, or BIS monitor; the Narcotrend, which is currently available only in Europe; the Patient State Analyzer; SNAP; and Auditory Evoked Potential Monitor (AEP Monitor, Danmetter Medical). The first one introduced into clinical use, the one that has received the most clinical use, and the most commonly used monitor continue to be the Bispectral Index. The BIS is a modified electroencephalographic (EEG) monitor that uses a preset algorithm based on intraoperative EEG data obtained from adults who were anesthetized with agents that work through the γ-amino butyric acid (GABA) pathway. The BIS number is determined from three features of the EEG tracing: (1) the amplitude and frequency of the waves, (2) the synchronization of low- and high-frequency information, and (3) the percentage of time in burst suppression (flat EEG). The output of the processed EEG then provides a depth of sedation/anesthesia that is displayed numerically, ranging from 0 to 100, with 40 to 60 being the proposed suitable level of anesthesia to ensure amnesia and lack of recall. With the use of BIS monitoring, a decreased incidence of awareness has been demonstrated as well as a decrease in the total amount of anesthetic agent used.[35-37] Additional studies have suggested faster recovery times and faster discharge times from the postanesthesia care unit, both of which may translate into reduced perioperative costs.[37,38] Although not considered the standard of care for intraoperative monitoring, the ASA does recommend the availability of such monitors whenever general anesthesia is provided and suggests their use in clinical scenarios in which the patient may be at high risk for awareness, including situations involving patients who have had a previous episode of awareness. Given the success of such monitors in the perioperative arena, there is ongoing interest in the application of this technology in the ICU and the procedural sedation arena.[39-41]

Pharmacology of Anesthetic Agents

Local Anesthetic Agents

The local anesthetic agents can be divided into two chemically distinct classes: esters and amides. Local anesthetic agents in the amino ester class include procaine, chloroprocaine, and tetracaine. Amino amides include lidocaine, mepivacaine, prilocaine, bupivacaine, levobupivacaine, and ropivacaine. Clinically important differences between these two classes of local anesthetic agent include their site of metabolism, plasma half-life, adverse effect profile (CNS versus cardiac toxicity), and allergic potential (discussed later). Amino esters are metabolized by plasma cholinesterases, whereas amino amides undergo hepatic metabolism. As there is limited change in the activity of plasma cholinesterase based on chronologic and gestational age, there may be inherent safety advantages to using these agents in the neonatal population.

Local anesthetic agents block the sodium channels in the nerve membrane, thereby preventing depolarization and impulse propagation. The nonionized portion of the local anesthetic agent penetrates the lipid membrane, whereas the ionized portion

reversibly blocks the inner aspect of the sodium channel. Local anesthetic agents differ in intrinsic potency, onset of action, duration of action, and their ability to produce differential sensory and motor blockade. Potency is determined primarily by lipid solubility (high lipid solubility = potency).[42] Bupivacaine and tetracaine are examples of local anesthetic agents with high lipid solubility and hence high potency. The onset of action is determined primarily by the pK_a, with onset being most rapid in agents with a pK_a closest to the physiologic pH.[43,44] With a pK_a close to the physiologic pH, the percentage of the unionized form is greater, thereby increasing passage through the lipid nerve membrane. Lidocaine has a pK_a of 7.7 and at a pH of 7.4; 35% exists in the unionized base form, yielding a relatively rapid onset of blockade. In contrast, tetracaine has a pK_a of 8.6 with only 5% in the unionized form at a tissue pH of 7.4, resulting in a slower onset of blockade than lidocaine. Lastly, the duration of action is determined primarily by the degree of protein binding to receptors in the sodium channel.[45] High protein binding and therefore a prolonged duration of action are characteristic of bupivacaine, levobupivacaine, tetracaine, and ropivacaine. Duration of action is also influenced by the degree of vasodilation produced by the local anesthetic.[45-47] Vasodilatation results in increased blood flow to the area and therefore an increased removal of the agent from the depot in the tissues. The local anesthetic agents also differ in their differential effects on sensory versus motor nerves. Bupivacaine and ropivacaine demonstrate this property, which is beneficial for postoperative analgesia, whether provided as a single injection or administered through an epidural catheter. The differential blockade allows patients to ambulate, as they have limited motor weakness, and yet sensory blockade provides analgesia.[47]

When performing regional anesthesia, the goal is to place the local anesthetic agent close to the nerve or plexus that needs to be anesthetized. An addition to the armamentarium of the anesthesiologist has been the use of ultrasound to visualize the individual nerve roots or the plexus that is to be anesthetized.[48-52] This technology is also being used for neuraxial techniques including spinal and epidural anesthesia. In both the adult and pediatric population, the use of ultrasound has been shown to increase the success rate of various regional anesthetic techniques and to result in successful blockade with a decreased dose of the local anesthetic agent.

Given the catastrophic effects of local anesthetic toxicity, mechanisms to avoid it and prevent its occurrence are mandatory during the performance of regional anesthetic techniques in infants and children. Epinephrine (0.5 μg/ml or a concentration of 1 : 200,000) is added to the local anesthetic solution during performance of a regional anesthetic technique to cause local vasoconstriction, thereby decreasing the vascular absorption of the drug and also serving as a marker of inadvertant systemic injection.[53-55] Even with negative aspiration for blood, there is the potential for inadvertant intravascular administration. As such, the use of a test dose is common practice for both peripheral and neuraxial blockade as a means of identifying inadvertant systemic injection of the local anesthetic solution. Epinephrine is added in a 1 : 200,000 concentration (5 μg/mL). In adults, the test dose includes 3 mL or 15 μg of epinephrine; in the pediatric population, 0.1 mL/kg of the local anesthetic solution is administered, which results in the delivery of 0.5 μg/kg of epinephrine. If this amount of epinephrine is injected intravascularly, it can generally be detected by changes in heart rate, blood pressure, or the ST-T wave

segments of the electrocardiogram and thereby alert the practitioner that inadvertant intravascular injection is occurring.[4]

The site of injection of the local anesthetic agent also has a significant impact on the clinical effects including the duration of action and vascular uptake (plasma concentrations). The shortest duration of action occur with either intrathecal injection for spinal anesthesia or subcutaneous administration. The longest duration of action and onset of blockade are seen with major peripheral nerve blocks (brachial or lumbar plexus blockade). The highest plasma concentration occurs with an intercostal nerve block or interpleural analgesia followed, in order, by caudal epidural, lumbar or thoracic epidural, brachial plexus, peripheral nerve blockade, subarachnoid, and subcutaneous infiltration.[56]

The greatest risk of morbidity and mortality related to the use of local anesthetic agents is the potential to achieve a toxic plasma concentration of the drug. Local anesthetic-induced systemic toxicity affects the central nervous system (CNS) and the cardiovascular (CV) system. The differential effects on these two organ systems and the plasma concentration at which toxic effects are noted vary according to the agent. With most local anesthetic agents, CNS toxicity occurs at doses and blood levels below those that produce CV toxicity. The latter provides some degree of safety, as the CNS symptoms (seizures) are generally more amenable to treatment than the CV effects (arrhythmias and conduction blockade). Death from local anesthetic toxicity is most commonly the result of the cardiovascular effects of these agents with adverse effects on cardiac electrical and mechanical activity.[57] Bupivacaine produces cardiac arrhythmias by inhibiting the fast sodium channels and the slow calcium channels in the cardiac membrane. Hypercarbia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic effects of high plasma concentrations of local anesthetic agents. These effects are so profound that resuscitative measures for ventricular tachycardia/fibrillation including standard ACLS protocols may be ineffective. Anecdotal case reports have suggested the potential role of various agents such as amiodarone for refractory ventricular arrhythmias or even the use of extracorporeal support. Anecdotal human data and animal studies have suggested that intralipid solutions may be used to bind the local anesthetic agent thereby resulting in the return of spontaneous circulation. Current recommendations from the ASA include ready access to 20% intralipid solutions whenever large doses of local anesthetic agents are used for regional anesthetic techniques.[58,59] Given the risks of morbidity and mortality from local anesthetic toxicity, avoidance of toxicity is the goal through the careful calculation of the dose, use of the lowest necessary dose (concentration and volume), use of a test dose with epinephrine to identify inadvertant intravascular injection, intermittent aspiration to identify vascular penetration, and slow incremental injection of the dose.

Intravenous Anesthetic Agents

The intravenous anesthetic agents in common clinical use include the barbiturates (thiopental, methohexital, and thiamylal), propofol, etomidate, and ketamine. Of note, although the ultra–short-acting barbiturates, thiopental and thiamylal, were frequently used for the induction of anesthesia, their availability within the United States is limited and they no longer play a major role in anesthetic practice. The remaining ultra–short-acting barbiturate, methohexital, is still available in the United

States but has limited use for anesthetic induction. Given its stimulatory effects on the electroencephalogram, it remains a niche agent for sedation during electroconvulsive therapy (ECT) in the adult population.

Propofol, ketamine, and etomidate are the intravenous anesthetic agents used most commonly by bolus administration to induce anesthesia. Propofol is also used as a continuous infusion usually in combination with a synthetic opioid infusion (remifentanil, fentanyl, sufentanil) for total intravenous anesthesia (TIVA) or by itself as a continuous infusion to provide MAC while maintaining spontaneous ventilation for procedural sedation. The latter is a commonly employed technique for procedural sedation outside of the operating room during nonpainful radiologic imaging such as MRI.

The barbiturates, propofol, and etomidate mediate their anesthetic properties through interactions with the $GABA_A$ receptor complex. These interactions lead to enhanced activity of the inhibitory neurotransmitter system, GABA.[60-63] Activation of the $GABA_A$ receptor increases the transmembrane movement of chloride resulting in hyperpolarization of the postsynaptic cell membranes. Ketamine's analgesic and anesthetic effects are the result of its interactions with the *n*-methyl-D-aspartate (NMDA) system, which is activated by glutamate, an excitatory transmitter, as well as other sites within the CNS including those involved with opioid and cholinergic transmission.[64-66]

The intravenous anesthetic agents result in somewhat varying end-organ effects. The barbiturates, propofol, and etomidate reduce cerebral metabolism ($CMRO_2$), cerebral blood flow (CBF), and intracranial pressure (ICP). As such, they are valuable agents in the practice of neuroanesthesia or in critically ill patients with increased ICP. When compared with propofol or the barbiturates, etomidate may be preferred in patients with abnormal cardiovascular function as it provides greater hemodynamic stability. Etomidate maintains cerebral perfusion pressure (cerebral perfusion pressure [CPP] = mean arterial pressure [MAP] − ICP), whereas propofol and the barbiturates may decrease MAP through their effects on systemic vascular resistance (vasodilatation) as well as direct negative inotropic properties. Thiopental and perhaps etomidate and propofol may possess neuroprotective properties secondary to reducing $CMRO_2$, which improves the ability of the brain to tolerate incomplete ischemia during procedures such as carotid endarterectomy or the temporary occlusion of cerebral arteries during an aneurysm repair.[67,68]

The effects of ketamine on ICP remain controversial with the older literature suggesting that ketamine may directly increase cerebral blood flow and ICP. However, more recent studies suggest that ketamine has limited effects on CBF and ICP, especially when given in combination with other anesthetic agents including midazolam.[69-71] It has been postulated that the older literature suggesting an increase in ICP with ketamine was related to depression of ventilation and alterations in $PaCO_2$ rather than direct effects on CNS dynamics. Given concerns related to the effects of etomidate on the endogenous production of corticosteroids, ketamine is being used more commonly for endotracheal intubation in patients with traumatic brain injury (discussed later).[72]

Propofol, midazolam, and the barbiturates have similar effects on the EEG. Initial, low doses with low brain concentrations result in transient high-frequency activity followed by lower-frequency, higher-amplitude waveforms at high brain

concentrations and eventually burst suppression and even electrical silence with high enough doses. These effects, which are similar to those produced by the potent inhalational anesthetic agents, have been studied in enough detail and are consistent enough that algorithms have been developed that can analyze the EEG patterns and thereby determine the depth of anesthesia (discussed earlier). These intravenous anesthetic agents have anticonvulsant properties. The barbiturates, midazolam, and propofol have been incorporated into algorithms for the treatment of refractory status epilepticus.[73,74] On the other hand, etomidate can produce involuntary myoclonic movements from an imbalance of inhibitory and excitatory influences in the thalamocortical tract. Etomidate also stimulates the EEG resulting in increased amplitude and frequency.[73,74] Myoclonic movements and opisthotonic posturing have also been reported following the administration of propofol, although there is no associated activation of the EEG. Rather it is postulated that these effects occur from antagonism at glycine receptors in subcortical and spinal structures.

The intravenous anesthetic agents also have dose-dependent effects on ventilatory function. Thiopental, propofol, etomidate, and midazolam result in a decrease of tidal volume and minute ventilation as well as a rightward shift of the CO_2 response curve. As with many end-organ effects of the anesthetic agents, the respiratory depressant effects may be magnified in patients with comorbid conditions (chronic respiratory or cardiovascular disease) and when coadministered with other medications that are respiratory depressants (inhalational anesthetic agents, opioids, phenothiazines). Given these effects on central control of ventilation, a transient period of apnea may occur following an anesthetic induction dose. In contrast to the respiratory effects of propofol, etomidate, and the barbiturates, in the absence of comorbid diseases, ketamine can generally be expected to result in minimal respiratory depression with preservation of airway protective reflexes.[75,76] Ketamine also stands apart from the other intravenous anesthetic agents in that the release of endogenous catecholamines following its administration results in bronchodilatation, thereby making it a suitable induction agent in patients who are actively wheezing or at risk for reactivity during airway manipulation.[77] Propofol has also been shown to have beneficial airway effects in both clinical and animal studies of airway reactivity, making it a suitable agent for anesthetic induction and endotracheal intubation of patients with altered airway reactivity.[78-81] The proposed mechanism for these effects is a decrease of intracellular inositol phosphate resulting in a depression of intracellular calcium availability.

During the induction or maintenance of anesthesia, the intravenous anesthetic agents can depress the cardiovascular system resulting in hypotension by various mechanisms. The mechanisms responsible for these hemodynamic effects include a reduction of central or peripheral autonomic nervous system activity, blunting of compensatory baroreceptor reflexes, decreased preload, systemic vasodilatation, and direct depression of myocardial contractility. Hemodynamic function during the induction of anesthesia may also be affected by comorbid cardiovascular disease, intravascular volume status, resting sympathetic nervous system tone, concomitant medications (angiotensin-converting enzyme inhibitors, β-adrenergic antagonists), and the administration of other agents including opioids and benzodiazepines. An induction dose of thiopental causes a variable decrease in cardiac output, systemic vascular resistance, and mean arterial pressure as a result of vasodilation as well as direct myocardial depression.[82] This effect is generally well tolerated in patients with

adequate cardiovascular function, but it can be exaggerated in the presence of preexisting cardiovascular disease or intravascular volume depletion necessitating the use of a lower dose of thiopental or preferably the use of alternative agents. Propofol demonstrates cardiovascular depressant effects similar to or greater than those of thiopental. Propofol is a direct myocardial depressant and reduces systemic vascular resistance. Significant cardiovascular responses following propofol are more common with high doses, in hypovolemic patients, in elderly patients, and in patients with significant cardiovascular disease.[83,84] The deleterious cardiovascular effects of propofol can be attenuated by the administration of calcium chloride (10 mg/kg).[85] Additional cardiovascular effects from propofol may result from its augmentation of central vagal tone leading to bradycardia, conduction disturbances, and asysole.[86,87] The negative chronotropic effects of propofol are more common when it is administered with other medications known to alter cardiac chronotropic function (fentanyl or succinylcholine). Although the relative bradycardia may be beneficial in elderly patients at risk for myocardial ischemia, it may be detrimental if cardiac output is heart rate dependent.

In contrast to the negative inotropic effects of propofol and the barbiturates, etomidate causes minimal cardiovascular depression and may be used for anesthetic induction in patients with significant cardiovascular disease.[88,89] As etomidate has little effect on systemic vascular resistance, it may be used in patients with cyanotic congenital heart disease in whom pulmonary blood flow is dependent on mean arterial pressure, those with a fixed stroke volume (aortic and mitral stenosis), and those with depressed myocardial contractility. Although suppression of adrenal cortical function occurs even following a single bolus dose of etomidate through inhibition of the activity of 17-α hydroxylase and 11-β hydroxylase, it remains controversial as to whether such effects are of clinical significance in the pediatric-aged patient.[90-92] The compelling data against the use of etomidate, especially in patients with possible sepsis, came from the Corticosteroid Therapy of Septic Shock (CORTICUS) trial.[93] Although the trial was intended to evaluate the efficacy of corticosteroid therapy on outcome in adults with septic shock and adrenal insufficiency, post hoc analysis revealed that patients who had received etomidate had a significantly higher mortality rate, which was not prevented by the administration of corticosteroids. These data suggest that etomidate should be avoided in patients with sepsis or septic shock until there are more definitive data. Although the use of etomidate has decreased in many centers or even been totally eliminated, given its beneficial effects on hemodynamic function and intracranial dynamics, until further data are available it seems prudent to consider its use in critically ill patients outside of the sepsis arena. Perhaps the greater risk may be the potential for cardiovascular collapse when other agents with significant cardiovascular effects are used in critically ill patients. Although still used as a single induction dose in patients with comorbid cardiovascular disease, repeated doses or continuous infusions are not recommended.

The cardiovascular effects of ketamine are different from those of the other intravenous anesthetic agents. Ketamine stimulates the cardiovascular system by activation of the sympathetic nervous system and the release of endogenous catecholamines.[94] Anesthetic induction doses of ketamine (1–2 mg/kg) generally increase heart rate and MAP. Although the indirect effects of ketamine include the release of endogenous catecholamines and stimulation of the sympathetic nervous

system, ketamine is a direct myocardial depressant. In most clinical scenarios, the indirect effects compensate for the direct negative inotropic effects. However, in critically ill patients who have depleted their endogenous catecholamines, cardiovascular collapse may occur.[95]

The pharmacokinetic profile of the intravenous anesthetic agents is characterized by a rapid onset of CNS effects secondary to the high lipid solubility of these agents and the high percentage of cardiac output perfusing the brain. The termination of the central CNS effect results from redistribution of the drug from the central to the peripheral compartment. It is not dependent on primary metabolism and elimination of the drug from the body. Most intravenous anesthetics are metabolized in the liver and excreted in the kidney. Some metabolites are active, such as desmethyldiazepam (diazepam) and norketamine (ketamine), and may result in prolonged effects especially with repeated dosing or the use of continuous infusions. There is a wide variation in the elimination half-lives of intravenous anesthetic agents because of differences in clearance. Drugs with short elimination half-lives include propofol, etomidate, ketamine, and midazolam, whereas thiopental has a long elimination half-life. Propofol is widely used, especially in ambulatory surgery centers, because of its short duration of action, fast recovery time, and early discharge potential.[96,97] This rapid recovery results in less *hangover effect* or residual drowsiness following outpatient surgical procedures, thereby facilitating return to work and resumption of activities of daily life. However, these short-acting agents (propofol, midazolam) demonstrate a pharmacodynamic principle known as the *context-sensitive half-life*. Although their offset is rapid following brief infusions or bolusing dosing, with prolonged infusions over days, their duration of action becomes more like that of long-acting agents with a prolonged recovery when the infusion is discontinued.

Opioids

There are various roles for the opioids in the perioperative and anesthetic treatment of patients. The commonly used opioids are agonists at the μ (mu) opioid receptors located at discrete sites throughout the spinal cord and the CNS.[98] These agents are generally combined with either an inhalational anesthetic agent or an intravenous anesthetic agent for TIVA (discussed earlier). This combination is necessary because even when administered in doses sufficient to produce profound analgesia and apnea, the opioids do not consistently produce amnesia in healthy patients.[99] Intraoperatively, the opioids are used to blunt the sympathetic stress response to surgical trauma, decrease the requirements for inhalational or intravenous anesthetic agents, and provide postoperative analgesia.

Although discrete differences in the chemical structure exist in the intravenous opioid agents, when used clinically, the clinically relevant differences include their potency, onset of action, duration of action, lipid solubility, hemodynamic effects, and metabolic fate (Table 131.3).[100,101] During the conduct of general anesthesia, the synthetic agents including fentanyl and its derivatives are frequently chosen given their brief duration of action, ability to effectively blunt hemodynamic changes related to the surgical stress response, and limited cardiovascular effects. However, other opioids including morphine or hydromorphone may be chosen given their longer duration of action with the ability to provide postoperative analgesia during the transition from general anesthesia to the awake state (emergence). Morphine is

the least lipophilic of the commonly used opioids and therefore it has a slower onset of action than the more lipophilic synthetic opioids such as fentanyl. Morphine, like all of the opioids except for remifentanil, undergoes hepatic metabolism. In part, morphine is converted to morphine-6-glucoronide (M6G), a water-soluble metabolite with a potency far greater than that of the parent compound. However, given that it is water solubile, M6G does not rapidly pass through the blood-brain barrier into the CNS and therefore has limited clinical effects. In patients with renal insufficiency or failure, a significant amount of M6G can accumulate and result in respiratory depression.

TABLE 131.3

Potency and Half-Life of Opioids

Agent	Potency	Half-Life	Active Metabolites
Morphine	1	2-3 hours	Yes
Meperidine	0.1	2-3 hours	Yes
Hydromorphone	5	2-4 hours	No
Oxymorphone	10	2-4 hours	No
Methadone	1	12-24 hours	No
Fentanyl	100	20-30 minutes	No
Sufentanil	1000	20-30 minutes	No
Alfentanil	20	10-15 minutes	No
Remifentanil	100	5-8 minutes	No

Meperidine has a potency that is approximately 10% that of morphine with a similar half-life of 2 to 3 hours. Hepatic metabolism produces normeperidine, a metabolite that may accumulate in renal insufficiency with high plasma concentrations being epileptogenic. Given these concerns and the higher incidence of psychomimetic effects with meperidine, meperidine is rarely used for analgesia. Meperidine remains a common agent, administered in low doses (10 mg in an adult), to treat postanesthesia shivering.

Hydromorphone has a potency that is 6 to 8 times that of morphine with a half-life of 2 to 3 hours. As there are no active metabolites of hydromorphone, it may be an effective alternative to morphine in patients with renal insufficiency. When compared with morphine, hydromorphone causes less histamine release and may be an effective alternative agent when pruritus occurs with morphine use. In particular, hydromorphone may be the preferred agent for postoperative analgesia using patient-controlled analgesia in the older pediatric population.[102]

The synthetic opioids including fentanyl, sufentanil, and alfentanil are potent, highly lipid-soluble drugs with rapid onsets and short durations of action. Hepatic metabolism does not result in active metabolites. Fentanyl is 100 times as potent as morphine, whereas sufentanil has 10 times the potency of fentanyl (1000 times that of morphine). The pharmacokinetics of fentanyl and sufentanil are similar with both drugs being short acting at low doses and longer acting at higher doses. Alfentanil is less potent than sufentanil and fentanyl and has a rapid onset of action and a short duration of action. Because its elimination half-life is substantially less than that of sufentanil and fentanyl, it is suitable for multiple dosing and continuous infusions and is popular for ambulatory surgery in many centers. Remifentanil is the first true ultra–short-acting opioid.[103] It has a rapid onset of activity and undergoes ester metabolism, which results in a short, predictable duration of action. Its elimination half-life is 8 to 10 minutes, and its potency is comparable to fentanyl. It is

administered as a continuous infusion and remains short acting regardless of the duration of the infusion. Unlike the other opioids that have longer half-lives and a variable duration of effect in neonates and infants, the duration of action and half-life of remifentanil is constant across all age ranges, thereby making it a suitable agent in neonatal anesthesia when postoperative tracheal extubation is planned.[104-106]

Fentanyl, sufentanil, and alfentanil are common components of various general anesthetic techniques. They have replaced their predecessors (morphine, meperidine) because of their faster onset of action, shorter and more predictable duration of action, and minimal hemodynamic side effects. For general anesthesia they reduce the surgical stress response and the associated cardiovascular responses to endotracheal intubation and surgical stimulation. They potentiate the hypnotic effects of the inhalational and intravenous anesthetic agents. This dose-related decrease in the need for both intravenous and inhalational anesthetic agents facilitates recovery from prolonged anesthetic cases. High-dose opioid techniques are commonly used in cardiac surgery because the synthetic opioids produce a smooth induction process, provide hemodynamic stability, suppress the hemodynamic responses to various surgical stimulations, reduce the production of stress hormones, and provide a smooth transition to mechanical ventilation at the end of the case.

As with all medications used in the practice of anesthesia, there are several adverse effects related to opioid administration. Opioids produce a dose-related depression of the ventilatory response to CO_2 and blunt the response to hypoxia through a direct effect on the medullary respiratory centers.[107] Increasing plasma concentrations result in a slowing of the respiratory rate that is initially offset by an increase in tidal volume. Equianalgesic doses of all opioids (fentanyl, morphine, meperidine, etc.) produce equivalent degrees of respiratory depression. Opioid-induced respiratory depression is antagonized by pain, movement, and opioid antagonists such as naloxone. When postoperative respiratory depression related to opioids occurs, small incremental doses of naloxone (1 μg/kg every 2 to 3 minutes) may be used to reverse opioid-induced respiratory depression without reversing analgesia. This is opposed to the dose of naloxone (10 μg/kg) that is commonly used for opioid overdose in the emergency department setting. Given that the clinical half-life of naloxone is 20 to 30 minutes, repeated doses or a continuous infusion may be needed if longer-acting opioids (morphine, meperidine, or hydromorphone) have been administered. Longer-acting opioid antagonists (nalmefene) are now clinically available; however, there is limited clinical experience with their use in the pediatric population. Opioid reversal using naloxone, especially with larger doses, can result in undesirable or dangerous hemodynamic responses such as hypertension, tachycardia, and myocardial infarction. The potential for such effects must be weighed against the anticipated benefits of opioid reversal.

Opioids generally produce minimal cardiovascular effects at usual analgesic doses. With higher doses, when combined with other anesthetic drugs, or in patients with comorbid features, opioids may produce bradycardia and a decrease in systemic vascular resistance (SVR) resulting in hypotension. The synthetic opioids may result in bradycardia from stimulation of the central nuclei of the vagus nerve leading to prolonged atrioventricular conduction and direct depression of the sinoatrial node, whereas peripheral vasodilation results from depression of the vasomotor centers in the medulla.[108,109] Patients with elevated levels of sympathetic

tone (hypovolemia, congestive heart failure) are more likely to become hypotensive after opioids. Although anesthetic techniques using high doses of the synthetic opioids may result in bradycardia and peripheral vasodilation, given that there is no direct negative inotropic effects, these techniques are effective for patients with myocardial pathology including patients undergoing cardiovascular surgery in whom a high dose of fentanyl (25–75 μg/kg) is a frequently chosen anesthetic technique. Decreases in blood pressure with such techniques result from a decrease in SVR and are easily treated with a direct-acting α-adrenergic agonist such as phenylephrine. Morphine may result in more profound venodilatation leading to decreased venous return, decreased cardiac output, and hypotension. Meperidine, given its structural similarity to atropine, may result in a mild tachycardia.

Nitrous Oxide

A unique aspect of intraoperative anesthetic care is the administration of inhalational anesthetic agents including nitrous oxide (N_2O), halothane, enflurane, isoflurane, sevoflurane, and desflurane. Although their anesthetic properties are similar, the potent inhalational anesthetic agents can be divided into two chemically distinct classes: alkanes and ethers. Halothane is an alkane (a two-carbon chain), whereas the other four agents (enflurane, isoflurane, desflurane, and sevoflurane) are ethers. The potent inhalational anesthetic agents are volatile liquids and are administered to the patient via a vaporizer on the anesthesia. Nitrous oxide is administered either from a central hospital source or from E cylinders on the anesthesia machine. Flows of nitrous oxide and oxygen are mixed in varying concentrations and then directed through the vaporizer to pick up the desired concentration of the potent inhalational anesthetic agent.

The potency of inhalational anesthetic agents is measured by minimum alveolar concentration (MAC). MAC is defined as the percentage of the inhalational anesthetic agent required to prevent 50% of patients from moving in response to a surgical stimulus. The lower the MAC, the more potent the inhalational agent. Halothane is the most potent inhalational anesthetic agent, followed, in order, by isoflurane, enflurane, sevoflurane, and desflurane. Nitrous oxide has a low potency (MAC of 110%) and must be combined with other intravenous sedatives/analgesics/anesthetics or a potent inhalational anesthetic agent to fulfill the prerequisites (unconsciousness, analgesia, muscle relaxation, decrease in sympathetic nervous system activity) of a general anesthetic. As 1.5 to 2.5 MAC of an agent is required to maintain anesthesia solely with a potent inhalational anesthetic agent, in most clinical scenarios, 1 to 1.5 MAC of an inhalational anesthetic agent is combined with N_2O, opioids, or intravenous anesthetic agents to provide maintenance anesthesia during a surgical procedure.

Nitrous oxide (N_2O) was the first of the inhalational anesthetic agents to be discovered. Although there has been a decline in its use with the introduction of the newer inhalational anesthetic agents with low blood-gas solubility coefficients (desflurane, sevoflurane), it still used as a component of intraoperative anesthetic regimens and in some centers for procedural sedation.[110] Depending on the concentration administered, N_2O can provide sedation and analgesia or a weak anesthetic level. In concentrations of 70%, N_2O will render the majority of patients

amnestic and provide moderate to significant analgesia. However, only minor surgical procedures can be performed with N_2O and O_2 alone, and its amnestic properties are not a given, thereby necessitating its combination with other agents. When used as the sole agent, N_2O causes minimal respiratory and cardiac depression.[111] Recovery from N_2O sedation is rapid given its low blood-gas solubility coefficient. During recovery, high concentrations of O_2 are needed to avoid diffusion hypoxia.[112] As N_2O diffuses from the blood into the alveoli, its alveolar concentration rises, thereby decreasing the effective concentration of oxygen, which can lead to *diffusion hypoxia.* When used for procedural sedation on repeated occasions, N_2O can lead to inactivation of methionine synthetase, an enzyme necessary for vitamin B_{12} metabolism leading to bone marrow impairment with megaloblastic anemia and deterioration of the posterior columns of the spinal cord and neurologic impairment.[113,114] These effects may occur not only in patients but also in health care workers with chronic exposure, thereby mandating effective scavenging of exhaled gases to avoid environmental pollution whenever N_2O is administered. Given solubility differences, N_2O diffuses into and expands gas-containing closed spaces in the body (obstructed bowel, pneumothorax, middle ear, pneumocephalus, and air embolus).[115] There has been decreased use of N_2O for intraoperative anesthetic care related to reports from the adult literature regarding the potential for increased cardiovascular morbidity and an increased incidence of surgical site infections.[116,117] The potential for cardiac morbidity including myocardial infarction has been postulated to relate to N_2O's effect on methionine synthetase with increased homocysteine levels leading to enhanced platelet function. Given such concerns and the availability of short-acting inhalational agents allowing for rapid recovery from general anesthesia, the use of nitrous oxide has diminished.

Volatile Anesthetic Agents

When administered in appropriate inspired concentrations, all of the potent inhalational anesthetic agents (halothane, isoflurane, enflurane, desflurane, and sevoflurane) provide the basic components of a general anesthetic including amnesia, analgesia, skeletal muscle relaxation, and control of the sympathetic nervous system. Despite their use for more than 150 years in clinic anesthetic care, the exact site and mechanism of action of these agents remain elusive. Research suggests that the primary mechanism may reside in the stabilization of critical proteins, possibly the receptors of neurotransmission.[118] Although these agents provide general anesthesia, their end-organ effects can be varied, thereby dictating their use in various clinical scenarios. In infants and children, given the potential stress that may be inflicted by placement of an intravenous cannula, anesthetic induction may be carried out by the inhalation route with placement of the intravenous cannula after the patient is anesthetized. As halothane and sevoflurane are less pungent to the airway than the other agents, they are the only agents used for the inhalation induction of anesthesia. Although halothane had been the time-honored agent for inhalation induction of anesthesia in infants and children, it has been removed from the market and replaced with sevoflurane due to its significantly lower incidence of bradycardia, myocardial depression, and cardiac arrest. In fact,

surveys evaluating the etiology of cardiac arrest during general anesthesia in infants and children have implicated halothane as the primary factor responsible for many of these events.

All of the potent inhalation anesthetic agents cause a dose-related depression of cardiovascular and respiratory function. With increasing anesthetic depth, there is a rightward shift of the CO_2 response curve with a progressive decrease in alveolar ventilation characterized by a reduction in tidal volume in spontaneously breathing patients and an increase in $PaCO_2$. Beneficial effects on the airways include a direct effect on bronchial smooth muscle with bronchodilatation making them an effective agent both intraoperatively and outside of the operating room for the treatment of patients with refractory status asthmaticus.[119]

The potent inhalational anesthetic agents decrease mean arterial pressure, myocardial contractility, and myocardial oxygen consumption. The specific change in cardiac output, systemic vascular resistance, and heart rate varies from agent to agent and with the inspired concentration of the agent that is administered. Isoflurane and desflurane result primarily in vasodilatation and a decrease in SVR with reflex tachycardia. Direct negative chronotropic effects predominate with sevoflurane and halothane leading to a lowering of heart rate. As mentioned previously, this effect is less with sevoflurane than with halothane. Because of its alkane structure, halothane sensitizes the myocardium to catecholamines and can cause dysrhythmias, especially when there is associated hypercarbia or high circulating catecholamines. The latter was of clinical significance when epinephrine-containing local anesthetic agents were administered to patients anesthetized with halothane.

The potent inhalational anesthetic agents cause a dose-dependent decrease in CNS activity, depressing EEG activity, and reducing cerebral metabolic oxygen consumption. Enflurane and sevoflurane can activate the EEG and produce clinical and EEG evidence of seizure activity at high concentrations. Such problems are exacerbated by the presence of hypocarbia, which may occur if there is hyperventilation during anesthetic induction. Despite such effects, there is no contraindication to the use of sevoflurane in patients with an underlying seizure disorder. CBF increases via a reduction in cerebral vascular resistance, which can lead to an elevation of ICP in patients with compromised intracranial compliance. The effect on ICP is least with isoflurane and can be blunted by hyperventilation and hypocarbia. These effects make isoflurane a common choice for neurosurgical anesthesia. The volatile anesthetic agents also have peripheral neuromuscular effects, potentiate the effects of the neuromuscular blocking agents, and along with succinylcholine are triggering agents for malignant hyperthermia.

In addition to the parent compound, metabolic products may be responsible for the toxicity of the potent inhalational anesthetic agents. Fifteen percent to 20% of halothane is metabolized compared to 5% to 10% for sevoflurane, 2% to 3% for enflurane, 0.2% for isoflurane, and less than 0.1% for desflurane. In the early days of inhalational anesthesia, hepatic toxicity was a significant concern and existed into the modern era with halothane. Hepatotoxicity occurs from an immune-mediated reaction following exposure to halothane, enflurane, isoflurane, or desflurane.[120-123] However, given the limited metabolism of enflurane, isoflurane, and desflurane, the risk of hepatotoxicity is extremely low. The mechanism of hepatotoxicity relates to the metabolic product trifluoroacetic acid (TFA) acting as a hapten. It binds to

hepatocytes and induces an immune-mediated hepatitis. The metabolic pathway of sevoflurane is different and does not result in the production of TFA. Risk factors for halothane-hepatis include prior anesthetic exposure, female gender, age ≥35 years, and obesity.[124,125]

Albeit rare, specific issues related to renal function must be considered during anesthetic care. Importantly, alterations related to cardiac output due to the inhalational anesthetic agents may secondarily decrease renal blood flow and result in renal damage. As with other end organs, the kidneys may be damaged by the agent itself or its metabolites. Additionally, both enflurane and sevoflurane contain flouride around their carbon atoms, which can be released during metabolism.[126] Fluoride concentrations in excess of 50 μmol/L can result in decreased glomerular filtration rate and renal tubular resistance to vasopressin with nephrogenic diabetes insipidus. Although high levels of serum fluoride may occur following the prolonged administration of sevoflurane, clinical signs of nephrotoxicity are extremely rare. This is postulated to be the result of the low blood : gas partition coefficient of sevoflurane and its rapid elimination from the body or the fact that sevoflurane unlike older agents such as methoxyflurane does not undergo metabolism in the kidney but only in the liver. Therefore unlike methoxyflurane, there is no local renal release of fluoride thereby limiting the risk of toxicity. Although high serum flouride concentrations have been documented with prolonged enflurane administration, this agent is no longer commonly used in clinical anesthesia practice. An additional concern regarding the potential nephrotoxicity of the potent inhalational agents is unique to sevoflurane, in particular a unique metabolite, a vinyl ether also known as compound A. Compound A is produced during the metabolism of sevoflurane and its reaction with the soda lime in the carbon dioxide absorber of the anesthesia machine.[127-129] Compound A concentrations are increased by several factors including a high inspired concentration of sevoflurane, low fresh gas flows through the system (less than 2 liters per minute), increasing temperatures of the soda lime canister, decreased water content of the CO_2 absorbent, and high concentrations of potassium or sodium hydroxides in the CO_2 absorbent. Although of potential concern when studied in laboratory animals, there are no clinical data to suggest the nephrotoxic potential of compound A, thereby suggesting that such concerns should not limit the use of sevoflurane even in patients with preexisting renal dysfunction.

Neuromuscular Blocking Agents

The reader is referred to Chapter 133 for a complete review of the use of neuromuscular blocking agents (NMBAs). The following section deals briefly with the aspects of NMBA administration that relate specifically to perioperative anesthetic care. Intraoperatively, skeletal muscle relaxation may be required for the successful completion of a surgical procedure (exploratory laparotomy), may be required briefly for endotracheal intubation, or may be used to ensure patient immobility in situations where inadvertant movement may be detrimental (craniotomy). Although frequently administered during the perioperative period, many surgical procedures can be performed without the administration of NMBAs. NMBAs have no effect on the level of consciousness, provide neither amnesia nor analgesia, and do not alter the dose of other medications required to induce and

maintain general anesthesia. When NMBAs are used, the patient requires an adequate level of general anesthesia and, in the intensive care unit, an adequate level of sedation. This is especially important because clinical signs of inadequate anesthesia (movement) are abolished. It is also important to recognize that the airway must be controlled when NMBAs are used. These agents are contraindicated if there is any concern regarding one's ability to control ventilation and provide endotracheal intubation. One additional caveat regarding the administration of NMBAs is that although problems are rare, NMBAs are high on the list of agents responsible for intraoperative anaphylactoid reactions (along with antibiotics and latex). Albeit rare, these anaphylactoid reactions are most common with succinylcholine and rocuronium.

Neuromuscular blockade may be used only to facilitate endotracheal intubation or may be continued throughout the surgical procedure to provide surgical relaxation. When ongoing neuromuscular blockade is required, incremental doses, which are approximately one-fourth to one-fifth of the initial intubating dose, are administered based on the response obtained using neuromuscular blockade monitoring. Alternatively, a continuous infusion of short- or intermediate-acting agents is occasionally used. Given that repetitive doses or an infusion may result in excessive levels of neuromuscular blockade, monitoring of neuromuscular transmission is used to predict optimal conditions for endotracheal intubation, adequacy of surgical muscle relaxation, effectiveness of reversal of neuromuscular blockade, and to guide dosing of NMBAs during intraoperative care. The goal of such monitoring is to allow incremental titration of NMBAs to maintain the desired level of blockade while maintaining sufficient neuromuscular function to allow reversal of a residual neuromuscular blockade at the completion of the surgical procedure. To monitor a neuromuscular blockade, a supramaximal electrical stimulation from a peripheral nerve stimulator is delivered to electrodes placed over the distribution of the peripheral nerve. This can be accomplished using the ulnar nerve at the wrist or elbow, the common peroneal nerve as it passes over the head of the fibula, or the facial nerve. As any of these methods involve electrical stimulation, they are painful and should only be performed in an appropriately anesthetized patient. Although various patterns of electrical stimulation of the peripheral nerve (single twitch, train-of-four [TOF], double burst suppression, tetanus, and posttetanic stimulation) have been advocated in the literature, TOF monitoring remains the technique used most commonly in clinical anesthesia practice. Two electrical stimuli are delivered each second for 2 seconds to give four twitches or a train-of-four. Despite its acceptance and use in everyday anesthesia practice, TOF monitoring is relatively nonspecific in that up to 70% to 80% of the acetylcholine receptors must be blocked in order to achieve any visible decrement in the TOF. The goal of monitoring is to ensure that some residual neuromuscular function is present at the completion of the surgical procedure so that the effects can be reversed. The goal of reversal is for the patient to sustain minute ventilation and maintain a patent airway to allow for tracheal extubation.[130,131] In most clinical circumstances, one or two twitches of the TOF must be present to allow for effective pharmacologic reversal. A TOF ≥0.7, where the fourth twitch is ≥70% the height of the first twitch, is evidence of adequate reversal. Other tests of adequacy of reversal include a sustained response to tetanus, a sustained head lift for 5 to 10 seconds, and strong grip strength. In infants, sustained hip flexion is a useful clinical sign. Patients demonstrating profound blockade (no

response to electrical stimulation) should not be reversed until some evidence of return of neuromuscular function has occurred. Despite adequate reversal, recurrence of partial paralysis resulting in respiratory insufficiency or upper airway obstruction may occur during the postoperative period.

Reversal of residual neuromuscular blockade is accomplished by the administration of medications that inhibit acetylcholinesterase (edrophonium, neostigmine, or pyridostigmine). With the inhibition of acetylcholinesterase, acetylcholine accumulates at the nicotinic (neuromuscular junction) and muscarinic sites, thereby increasing the competition between acetylcholine and the NMBA for the α subunits of the nicotinic cholinergic receptor. As these medications also inhibit acetylcholinesterase at muscarinic sites, they must be coadministered with an anticholinergic agent such as atropine or glycopyrrolate to prevent bradycardia or asystole. An inadequate response to the anticholinesterase medication with residual weakness may be secondary to excessive blockade at the time of reversal, allowing inadequate time since the administration of the reversal drug, an altered acid-base or electrolyte status, hypothermia, effects of other medications, or impaired clearance of NMBAs from the plasma secondary to renal or hepatic dysfunction.

Intraoperative Anesthetic Care

Maintenance Anesthesia

This chapter has discussed the perioperative care of a surgical patient from the preoperative evaluation through premedication, monitoring, and the induction of general anesthesia. Once the airway has been secured and ventilation/oxygenation established, maintenance anesthesia is provided for the duration of the surgical procedure. Given the variety of inhalational anesthetic agents, intravenous anesthetic agents, opioids, and NMBAs available, several combinations of agents can be used to provide the prerequisites of general anesthesia. The choice of agent varies widely and is determined by the personal preferences and experiences of the anesthesia provider, the patient's comorbid features such as his or her underlying cardiovascular function, the anticipated duration of the surgical procedure, the postoperative requirements (will the patient's trachea be extubated at the completion of the procedure, is ongoing postoperative analgesia required?), and the operative setting (is rapid turnover of cases desirable and are rapid awakening and hospital discharge needed?).

In most scenarios, the baseline level of anesthesia is provided by either a potent inhalational anesthetic agent or a propofol infusion and supplemented with intermittent dosing or a continuous infusion of an opioid. If ongoing neuromuscular blockade is required, a continuous infusion of a short-acting agent or intermittent dosing of an intermediate- to long-acting agent can be used. Although controlled ventilation is most commonly practiced, there are many surgical procedures for which spontaneous ventilation is acceptable. The use of spontaenous ventilation is more common in the outpatient setting where endotracheal intubation is less common and general anesthesia is provided using a mask or an LMA. In addition to the commonly monitored hemodynamic parameters, spontaneous ventilation provides an effective means of evaluating the depth of anesthesia through the assessment respiratory rate and pattern, thereby providing the optimal parameter

for the titration of opioids. When spontaneous ventilation is used, opioids can be dosed based on the patient's respiratory rate to ensure that an appropriate amount is administered to provide postoperative analgesia while avoiding overdosing and postoperative respiratory depression.

Intraoperative Fluid Management

In addition to monitoring hemodynamic and respiratory function, the anesthesiologist must also maintain fluid, electrolyte, and glucose homeostasis during anesthetic care. Intraoperative fluid management uses isotonic crystalloid solutions such as lactated Ringer (LR), normal saline (NS), or Plasmalyte to provide ongoing maintenance fluids and replace preoperative deficits, intraoperative third space losses, and blood losses when blood therapy is not necessary. Third space losses may be relatively trivial during superficial procedures (2–3 mL/kg/hr) or significant (10–15 mL/kg/hr) for intraabdominal procedures. Although generally considered an isotonic fluid, LR has only 130 mEq of sodium per liter and therefore is relatively contraindicated in patients at risk for cerebral edema such as the patient with a traumatic brain injury. Large volumes of NS, although effective in supporting the serum sodium, can result in a dilutional acidosis. These issues have led to the consideration of using a combination of NS and LR or the use of a more balanced solution such as Plasmalyte, which contains 140 mEq/L of sodium as well as physiologic amounts of chloride and gluconate/acetate as buffers. Given their distribution between the intravascular and extravascular space, if blood is not administered, blood loss is routinely replaced as 3 mL of crystalloid for each 1 mL of blood loss. Alternatives to isotonic crystalloid solutions include synthetic and natural colloids such as hydroxyethyl starch, albumin, or gelatins. The latter are not currently available in the United States. As with resuscitation in other areas, there are currently no studies demonstrating the superiority of any of these solutions over standard isotonic crystalloids, and it is likely that the crystalloid-colloid debate will continue for many years. Potential drawbacks to the use of hydroxyethyl starch solutions include the potential for platelet dysfunction when amounts greater than 15 to 20 mL/kg are administered. This reversible platelet dysfunction results from alterations in the efficacy of von Willebrand factor by the hydroxyethyl starch solutions. Furthermore, studies in the adult population have demonstrated an increased incidence of acute kidney injury when these products are administered intraoperatively.[132]

During the postoperative period, especially in pediatric patients, given the potential for the development of postoperative hyponatremia, only isotonic fluids should be administered.[133] Fluids with a lower tonicity are rarely if ever indicated. For short surgical procedures when a Foley catheter is not inserted, aggressive fluid therapy with replacement of the preoperative deficit is not necessarily required because bladder distention during emergence from anesthesia may be uncomfortable for the patient. Additionally, specific surgical procedures such as intracranial neurosurgical procedures and thoracic procedures or patients with underlying cardiovascular dysfunction may mandate that the patient "be kept dry" to improve the intraoperative and postoperative course. However, in many other surgical procedures especially intraabdominal cases, burn debridement, or other cases with significant third space losses, the administration of significant amounts of

isotonic crystalloids may be required to maintain intravascular volume status. Except for the neonatal population or patients chronically receiving parenteral nutrition fluids, dextrose-containing fluids are rarely administered. In high-risk patients, those receiving glucose containing fluids, and patients with diabetes mellitus, intermittent monitoring of blood glucose may be indicated. Such monitoring has been greatly facilitated by the ready availability of point-of-care testing for glucose. Although a review of the perioperative care of the diabetic patient is beyond the scope of this chapter, evidence in the adult literature has suggested that the postoperative outcome for such patients may be improved by tight perioperative glucose control.

Postoperative Care

Postoperative Analgesia

Various factors may interfere with the delivery of effective postoperative analgesia. Inadequate pain relief following surgery generally results from inappropriate methods of administration rather than ineffective analgesic agents. Although frequently used in the past for the delivery of opioids in the delivery of postoperative analgesia, the intramuscular route should be abandoned as several factors result in inadequate analgesia including variable absorption and unpredictable plasma opioid concentrations in addition to the child's reluctance to ask for pain medications due to the pain associated with intramuscular injections.[111] Fortunately, acute and postoperative analgesia has been an area of intense research, which has resulted in the development of new techniques and the refinement of treatment strategies.[134] Current modalities to provide better postoperative analgesia include intravenous patient-controlled analgesia (PCA), nurse-controlled analgesia (NCA), and the epidural or spinal application of local anesthetic agents or opioids.[135] Although introduced into the adult population, these techniques are now widely applied across all age ranges in pediatric patients. PCA involves the self-administration of small doses of opioids to obtain and maintain analgesia. Analgesia occurs when the plasma opioid concentration reaches the minimum effective analgesic concentration (MEAC). With PCA, patients are able to titrate the opioid to their own MEAC and can thereby maintain consistent analgesia.[136-138] Numerous studies have demonstrated improved analgesia, fewer adverse effects, and decreased opioid consumption with the use of PCA. Prior to the initiation of PCA, the patient receives a loading dose of the opioid administered either intraoperatively or postoperatively as multiple small doses of an opioid to achieve the MEAC. Once this is accomplished, the PCA is started and a dose of opioid is self-administered at a specific interval or lockout period (generally 5–10 minutes) as needed by the patient. Additionally, a continuous infusion can be added to the PCA regimen, although it has been suggested that this negates the safety feature of PCA in which no opioid is delivered if the patient is too sleepy to push the button. A modification of PCA is termed NCA, or nurse-controlled analgesia. With NCA, the same bolus and infusion are set, but the bedside nurse, instead of the patient, activates the device. NCA may be used in children who are too young or lack the needed cognitive function to use PCA. Although practices vary, continuous monitoring with pulse oximetry is generally recommended when PCA or NCA is used in the pediatric patient.

In addition to the opioids, acetaminophen and nonsteroidal antiinflammatory agents (NSAIDs) play a significant role in the control of postoperative pain. NSAIDs, acetaminophen, and salicylates act through the inhibition of the enzyme cyclooxygenase, thereby blocking the synthesis of prostaglandins. In distinction to opioids, these agents demonstrate a ceiling effect so that once a specific plasma concentration is achieved, no further analgesia is provided by increasing the dose. These agents are classified according to their chemical structure as (1) para-amino phenol derivatives (acetaminophen), (2) NSAIDs (ibuprofen), and (3) salicylates (acetylsalicylic acid, choline magnesium trisalicylate).[135] When considering the paraamino-phenol derivatives, acetaminophen has a significant role in the management of acute pain, whereas phenacetin is no longer used given its potential toxicity profile (renal papillary necrosis). Although previously available only as an oral or rectal medication in the United States, acetaminophen is now also available for intravenous administration. Commonly used NSAIDs include either ibuprofen for oral administration or ketorolac for intravenous administration. An intravenous preparation of ibuprofen has received approval of the Food and Drug Administration (FDA) for the treatment of pain and the control of fever in adults. The reader is referred to reference 139 for a more in-depth discussion of the prostaglandin synthesis inhibitors.[139]

Regional anesthetic techniques including either neuraxial blockade (epidural or spinal analgesia) or peripheral nerve blockade can be continued into the postoperative period to provide effective analgesia while avoiding the potential adverse effects associated with parenteral opioid therapy. Epidural and spinal local anesthetics provide profound analgesia; however, undesirable side effects of the use of high concentrations of local anesthetics include blockade of the sympathetic nervous system with hypotension, urinary retention, blockade of motor function, and risks of local anesthetic toxicity from systemic absorption. Epidural and spinal opioids can provide intense, segmental, localized analgesia without sensory, motor, or sympathetic nervous system effects, although their adverse effects profile may include respiratory depression, nausea, pruritus, sedation, and urinary retention. As a result, a combination of low-dose epidural local anesthetics and opioids are commonly used to take advantage of their synergistic effects and limit the side effects of each. Fentanyl and morphine are commonly used opioids, and bupivacaine is the usual local anesthetic of choice. The lipid solubility of the opioid predicts its clinical behavior. Fentanyl is very lipid soluble, penetrating the dura and rapidly binding to spinal cord opioid receptors, producing a fast onset of action but a short duration of action. Significant vascular absorption of fentanyl also occurs, decreasing its epidural effect and reducing its advantage over parenteral administration. Morphine is lipid insoluble and has a slower onset of action but a much longer duration of action. However, given its hydrophilic nature, morphine remains in the cerebrospinal fluid for a longer period of time with cephalad spread and the risks of delayed respiratory depression for up to 24 hours after neuraxial administration, thereby mandating ongoing monitoring of respiratory function during this time. Other methods of postoperative analgesia include the use of long-acting local anesthetic agents for either wound infiltration or peripheral nerve blockade. Examples of peripheral nerve blockade include brachial plexus blocks for upper extremity pain, femoral nerve blocks for femur and knee surgeries, sciatic nerve blocks for analgesia below the knee, and intercostal nerve blocks for thoracic and

abdominal surgeries. Options include the placement of a catheter to allow for a continuous infusion during the postoperative period and to provide long-term analgesia for up to 3 to 5 days.

Conclusions

The perioperative care of pediatric patients begins with the preparation of the operating room site as well as the preoperative evaluation of the patient. The complexity of the latter varies tremendously based on the presence of comorbid conditions. These coexisting conditions as well as the requirements of the surgical procedure influence the techniques used for intraoperative monitoring. In its simplest form, a general anesthesia includes amnesia, analgesia, muscle relaxation, and attenuation of the sympathetic nervous system's response to surgical trauma. The phases of general anesthesia include induction, maintenance, and emergence. The induction of anesthesia can be carried out with the intravenous administration of an anesthetic agent or via the inhalation route with an inhalational anesthetic agent such as sevoflurane. In pediatric patients, the inhalation induction of anesthesia is frequently chosen to avoid the need for obtaining intravenous access on an awake child. Following anesthetic induction, one progresses into the maintenance phase of general anesthesia. This may include the administration of intravenous agents, inhalational agents, or, most likely, a combination of the two. Following the successful completion of the surgical procedure, a plan is determined for the postoperative delivery of analgesia including some combination of intravenous opioids, agents to inhibit prostaglandin formation, or a regional anesthetic technique. For complex surgical procedures, tracheal intubation and mechanical ventilation may be continued into the postoperative period, whereas a combination of tracheal extubation and the resumption of spontaneous ventilation is the general rule for the majority of surgical procedures. Regardless of the type of anesthesia administered, close monitoring of hemodynamic and respiratory function is continued into the postoperative period either in the ICU or in a specialized postanesthesia care unit.

CHAPTER 132

Malignant Hyperthermia

Mihaela Visoiu, Ericka L. Fink, Barbara W. Brandom

PEARLS

- Malignant hyperthermia is characterized by hypermetabolism, although many causes of fever and muscle injury are not related to this condition.
- Risk factors for malignant hyperthermia include a family history of cardiovascular collapse during anesthesia with potent inhalation anesthetics, exertional heat stroke, or ryanodine receptor type 1 myopathy.
- Excessive metabolism produces uncontrollable hypercarbia and rapidly increasing temperature. Muscle rigidity and rhabdomyolysis are frequent. The clinical diagnosis may be confirmed by genetic testing.
- Treatment consists of the administration of repeated doses of 2.5 mg/kg of dantrolene until metabolism and muscle tone are normal. The patient is cooled aggressively if his or her temperature is >39°C. Hyperkalemia, myoglobinuria, disseminated intravascular coagulation, and cerebral edema are treated as needed. After the initial treatment, at least 1 mg/kg of dantrolene should be given every 4 to 6 hours, because 20% of patients experience an exacerbation or recrudescence of malignant hyperthermia within the first 24 hours of treatment.

The physician in the pediatric intensive care unit (PICU) may first encounter a patient with malignant hyperthermia (MH) in transfer from the operating room or from an outpatient facility where general anesthesia was given and treatment for acute MH began. Because 20% of patients experience a recurrence of MH in the 24 hours after the initial episode, close observation for a relapse of MH is warranted, and the administration of dantrolene for at least 24 hours after the initial episode is recommended. Alternatively, the ICU physician may be the first to entertain the diagnosis of MH in a patient admitted to the ICU for medical care or postoperative management.

MH is characterized by hypermetabolism, but many causes of fever and muscle injury are not MH. Regardless of the underlying cause, ICU management should be directed to control critical temperature and complications of rhabdomyolysis. The ICU physician should pursue common diagnoses while directing a diagnostic workup for the rare syndrome of MH.

Pathophysiology

In fulminant MH, a dramatic increase in the metabolic rate of genetically abnormal muscle results in muscle injury and potentially in multiorgan system failure. The underlying defect is a sudden, sustained increase in the concentration of calcium ion in the sarcoplasm.[1] Carbon dioxide (CO_2) production increases severalfold. Even with increased minute ventilation, it may not be feasible to maintain normocarbia. Lactic acid production overwhelms the body's buffering capacity. Increased O_2 demand and the concomitant sympathetic response stress the cardiovascular system. MH can progress rapidly to severe mixed acidosis, hyperkalemia, elevated temperature as in heat stroke,[2] and rhabdomyolysis. Renal failure, disseminated intravascular coagulation, cerebral edema, pulmonary edema, dysrhythmias, and cardiovascular collapse are potential consequences of fulminant MH. Before dantrolene, the mortality rate of MH was 70%. Symptomatic therapy including mechanical ventilation, active cooling, administration of bicarbonate, expansion of the intravascular volume, and treatment of dysrhythmias can prolong life during an episode of fulminant MH. However, the most effective therapy is intravenous dantrolene.[3]

In malignant hyperthermia–susceptible (MHS) mammals there is a defect in the ryanodine receptor type 1 channel (RYR1),[4] producing increased sensitivity to agonists[5,6] and decreased sensitivity to inhibitors. Furthermore, extracellular calcium entry (ECCE) is greater than normal in myotubes expressing MHS RYR1.[7] Dantrolene inhibits ECCE in both MHS and normal muscle. Store-operated calcium entry (SOCE) is another process, occurring after depletion of sarcoplasmic reticulum (SR) calcium, that moves extracellular calcium into the myoplasm. SOCE is coupled to RYR1 and decreased by dantrolene.[8]

Genetics

MH susceptibility is a syndrome with autosomal dominant inheritance, incomplete penetrance, and variable expressivity. The first-degree relatives of an MHS individual are treated as malignant hyperthermia susceptibility (MHS) until they have normal results after an in vitro muscle contracture test with halothane and caffeine (CHCT). Incomplete penetrance means that a person with an MHS mutation may not experience MH during the first or subsequent exposures to MH trigger agents. Multifactorial inheritance may be relevant.[9,10] Variable expressivity means that clinical symptoms of MH vary from minor to fulminant depending on factors such as the anesthetic agents, genetics, and temperature.[11] MHS episodes are more often observed in males.[12,13]

The primary genetic locus of MH (MHS 1) is the ryanodine receptor gene *(RYR1)* on chromosome 19q13.1. Variants associated with MHS are found throughout *RYR1*. In families with an MH-causative *RYR1* mutation, genetic analysis is a useful initial step in the diagnosis of MHS.[14,15] See www.mhaus.org for addresses of clinical diagnostic testing laboratories in the United States. This pathologic test has been useful to document MH susceptibility in postmortem muscle.[16]

Variants in the α-1 subunit of the DHPR gene *(CACNA1S)* on chromosome 1q32 have been associated with MH in ~1% of MHS families.[17] This is the MHS 5 locus.

See www.emhg.org for causative MH mutations at MHS 5 as well as MHS 1. A new locus of MHS is the STAC3 protein, encoded by *stac3* on chromosome 12, which is part of the excitation-contraction coupling mechanism in muscle. Abnormality in this protein has been associated with myopathy and MHS.[18] Although factors that modify the expression of MHS are not completely determined, active cysteines contribute to redox modulation and nitrosylation of RYR1.[19,20]

Clinical Recognition of a Malignant Hyperthermia Episode in Humans

The initial signs of an MH episode are nonspecific (Box 132.1).[21] The most frequent clinical signs of MH were hypercarbia (in 52%), hyperthermia (in 67%), and sinus tachycardia (in 62%) in 129 probands who later had muscle contracture tests diagnostic of MHS. Other MH signs noted in this group include masseter rigidity, total body rigidity, arrhythmia, mottling, and cyanosis.[22] This report from Canada is consistent with summaries of adverse metabolic and/or musculoskeletal reaction to anesthesia (AMRA) reports from the North American MH Registry.[12,23] Muscles may be rigid enough to pull the legs above the horizontal. Mixed respiratory and metabolic acidosis, hyperkalemia, myoglobinuria, and increased serum creatine kinase can be noted. However, rhabdomyolysis does not occur during every MH episode.[24]

Box 132.1

Positive Findings Consistent With Malignant Hyperthermia

History of recent exposure to trigger agent, including volatile anesthetic agents or succinylcholine

Family or personal history of malignant hyperthermia susceptibility

Total body rigidity

Masseter spasm

Inappropriately elevated (38.8°C) or rapidly increasing temperature (>1.5°C over 5 min)

Inappropriate tachypnea

Profuse sweating

Mottled, cyanotic skin

Dark urine, urine dipstick testing shows a positive result from blood without red cells in the sediment and no hemolysis

Unexplained, excessive bleeding

Unexplained ventricular tachycardia or fibrillation

Inappropriate hypercarbia (venous $PaCO_2$ >65 mm Hg, arterial $PaCO_2$ >55 mm Hg) if the patient is receiving positive pressure ventilation or is spontaneously breathing with greater than normal minute ventilation

Arterial base excess more negative than −8 mEq/L

Arterial pH <7.25

Potassium concentration >6 mEq/L

Creatine kinase >10,000 IU/L

In the ICU, a septic patient with kidney disease or chronic lung disease may exhibit fever, tachycardia, mixed respiratory and metabolic acidosis, and hyperkalemia. If sepsis, cardiovascular failure, central nervous system injury, heat stroke, or other medical or surgical conditions could have produced the abnormal vital signs, then these other diagnoses must be pursued and treated. MH may not be the most likely diagnosis in general, but recognition of recent exposure to volatile anesthetic agents or succinylcholine in a patient with a family history of problems after general anesthesia or muscular diseases associated with MH supports the presumptive diagnosis of MH.

In the 21st century MH signs usually occur later during anesthesia than they did when halothane and succinylcholine were commonly given.[23] MH can develop insidiously during a long anesthetic.[25] When the nonspecific early signs of MH are noted during induction of anesthesia, the potent inhalation anesthetics should be discontinued. This patient is considered to be MH susceptible until proved otherwise, and this episode is called abortive MH. Early termination of inhalation anesthetic agents in the presence of abortive MH may allow the syndrome to resolve spontaneously. On the other hand, there have been cases in which only mild signs of abortive MH occurred intraoperatively, but renal failure, hyperthermia, and death occurred postoperatively with no explanation other than MH.[26]

Potential Systemic Complications

Complications were noted in approximately 35% of 181 MH events reported to the North American MH Registry. These included changes in level of consciousness or coma in 9.4%, cardiac dysfunction in 9.4%, pulmonary edema in 8.4%, renal dysfunction in 7.3%, disseminated intravascular coagulation in 7.2%, and hepatic dysfunction in 5.6%.[12] Disseminated intravascular coagulation was associated with a 50-fold increased likelihood of cardiac arrest and an 89-fold likelihood of death.[27] The likelihood of any complication increased 2.9 times for every 2°C increase in maximum temperature and 1.6 times for every 30 minutes of time between the appearance of the first clinical sign of MH and the beginning of dantrolene administration.[12] Other complications reported were compartment syndrome, stroke after cardiac arrest, bilateral brachial plexopathy, generalized muscle weakness,

significant muscle loss, and prolonged intubation.[12]

Cerebral edema and coma have been reported in episodes of fulminant MH. Although normal metabolism of the brain was described during episodes of MH, O_2 supply to the central nervous system may be inadequate. Therefore supportive care to the patient during and after an episode of fulminant MH should include measures to document cerebral function and maximize cerebral perfusion.

Respiratory failure may occur early in an episode of fulminant MH. During an MH episode, desaturation can be also secondary to increased oxygen extraction. The workload of the respiratory system may be further increased by the occurrence of pulmonary edema. Pulmonary edema may be the result of capillary leak. It may be worsened by impaired cardiac contractility in the presence of acidemia. Cardiac dysrhythmias may occur in the presence of marked electrolyte abnormalities. In older patients, there may be foci of myocardial fibrosis as well. It has been hypothesized that such areas of fibrosis are the result of subclinical episodes of MH that produced increased levels of circulating catecholamines.[28] Cardiac contractility can be impaired.

Rhabdomyolysis occurs when the energy supply of the muscle is exhausted. Clinical manifestations include myalgias, swollen extremities, red-to-brown urine due to myoglobinuria, and elevated muscle enzymes. It is noteworthy that enzymes commonly elevated in the blood during hepatic injury including lactate dehydrogenase (LDH) and serum glutamic oxaloacetic transaminase (SGOT) will also be released from muscle when creatine kinase (CK) is markedly elevated. Rhabdomyolysis can produce electrolyte imbalance (hyperkalemia, hyperphosphatemia, hypocalcemia), metabolic acidosis, severe hyperuricemia, acute renal failure,[29] and compartment syndrome. Massive rhabdomyolysis, producing CK of greater than 20,000 IU/L, may occur in patients with underlying muscular diseases not necessarily related to MH. Thus rhabdomyolysis in the absence of increased metabolic rate, hypercarbia, and metabolic acidosis should not be assumed to be MH. However, the same treatment, including administration of dantrolene acutely, may be helpful to the myopathic patient who experiences rhabdomyolysis in the ICU. It is important to determine the underlying cause of rhabdomyolysis, because the implications for medical care differ depending on the pathologic diagnosis (eg, dystrophinopathy versus MH versus glycogen storage disease versus myotonia).

Hyperthermia in the Pediatric Intensive Care Unit

In the PICU, the most likely cause of fever is a bacterial infection,[30] but elevated temperature can also be the result of trauma, viral infection, lymphoma, leukemia, drug withdrawal, and allergy among other causes.[31] Inadequate fluid replacement predisposes to increased core temperature in children.[32] Excessive environmental heat with inadequate opportunity for evaporative heat loss can result in elevated temperature. In some cases, increased core temperature can be associated with tachycardia, increased expired CO_2, and metabolic acidosis, which are consistent with the expected increase in metabolic demand produced by fever. This can be so extreme as to mimic MH.

When hyperthermia occurs in a child with history of exposure to succinylcholine or volatile anesthetic agents, MH should be considered in the differential diagnosis. However, in a retrospective cohort study, conducted to analyze and identify the

causes of hyperthermia in the PICU over a 9-year period, Schleelein and associates noted that the incidence of clinically diagnosed MH was low (0.4%).[33] These cases were classified as "definite" or "probable" MH[21] by a Malignant Hyperthermia Association of the United States (MHAUS) MH Hotline consultant.[33] No information about CHCT or other pathologic tests that could support the diagnosis of MH for these patients is available.

Postoperative Fever

Postoperative fever (>38°C, >100.4°F) is common after surgery and usually resolves spontaneously. In establishing a differential diagnosis, it is helpful to consider the timing of fever onset: immediate, acute, subacute, or delayed. The causes may be infectious or noninfectious. The most common noninfectious cause is a medication reaction, followed by blood transfusion and by trauma suffered prior to surgery or as part of surgery. The fever due to MH usually starts within 30 minutes after administration of the triggering agent, but it has also been reported up to several hours later, after the anesthesia was discontinued.

Some clinical states, such as increased temperature after cardiac surgery, share some of the features of MH.[34] These situations may even include rhabdomyolysis, but it is the result of muscular injury from impaired circulation, not usually from a primary muscular disease.

Rhabdomyolysis

Rhabdomyolysis is characterized by muscle necrosis and the release of intracellular muscle constituents including CK, myoglobin, calcium, and potassium. CK levels greater than five times baseline are a sensitive definition of rhabdomyolysis. Rhabdomyolysis can be due to inherited or acquired causes, and the severity of clinical consequences ranges from asymptomatic increase of serum muscle enzymes to life-threatening hyperkalemia. The most frequent causes are trauma, overexertion, immobilization, alcoholism, vascular insufficiency, and orthopedic surgery. Grand mal seizures, delirium tremens, psychotic agitation, and amphetamine overdose can lead to rhabdomyolysis in individuals with otherwise normal muscle.[35] Some drugs such as HMG-CoA reductase inhibitors (statins) and colchicine are directly myotoxic.[35] Rhabdomyolysis may occur in patients with metabolic myopathies such as carnitine palmitoyltransferase deficiency, myophosphorylase deficiency (PYGM) or McArdle disease, myoadenylate deaminase deficiency (AMPD1), mitochondrial myopathy, or malignant hyperthermia susceptibility. Occasionally, patients with structural myopathies can develop acute rhabdomyolysis after strenuous exercise, after exposure to potent inhalation anesthetics, after exposure to other myotoxic drugs, or after a viral infection.

Treatment of an Episode of Malignant Hyperthermia

Remove Trigger Agents

When an episode of MH is suspected, inhalation anesthetic administration must be

stopped as soon as possible. High fresh gas flows of 10 L/min or more, or charcoal filters placed into the breathing circuit, are needed to eliminate residual anesthetic gas from the breathing circuit. If blood gas analysis documented significant respiratory and metabolic acidosis, dantrolene should be administered immediately and supportive treatment should be started as soon as possible (Box 132.2). Treatment of the life-threatening complications should not detract from the need to continue monitoring the metabolic status and the continued administration of dantrolene, in increasing doses if necessary, until the metabolic state is normal and muscles are flaccid.

Box 132.2

Management of an Acute Malignant Hyperthermia Episode in the Intensive Care Unit

1. Administer high-flow 100% oxygen via a non-rebreathing mask and consider endotracheal intubation.

2. For ventilated patients, administer FiO_2 of 1 and increase minute ventilation to control $Paco_2$.

3. Administer dantrolene (2.5 mg/kg intravenously) over 10 minutes and repeat, until acidosis and muscle rigidity have resolved. Repeat dantrolene (1 mg/kg) every 4 to 6 hours.

4. Initiate cooling with ice packs in the axillae and groin, decrease room temperature, use hypothermia blankets, iced intravenous saline solution (10 mL/kg over 10 min, repeated as needed), and lavage body cavities with cold saline solution if temperature is greater than 39°C. Stop cooling when core temperature falls to 38°C.

5. Correct metabolic acidosis with sodium bicarbonate (1–2 mEq/kg initially) and give subsequent doses based on base excess and body weight.

6. Administer calcium chloride (10 mg/kg) or calcium gluconate (100–200 mg/kg) to protect from cardiotoxicity associated with hyperkalemia.

7. Give regular insulin (0.1 U/kg) and glucose (0.3–0.5 g/kg) to correct hyperkalemia.

8. Administer lidocaine (1 mg/kg) to treat ventricular arrhythmias. Consider amiodarone (5 mg/kg IV) for refractory, stable ventricular tachycardia. Do not delay defibrillation or cardiopulmonary resuscitation if indicated by cardiovascular instability.

9. Maintain urine output of 2 mL/kg/hr with aggressive cold fluid administration, furosemide (0.5–1 mg/kg), and additional mannitol (0.25–0.3 g/kg) if needed.

. Consider quantitative end-tidal CO_2 monitoring.

. Monitor core temperature (pulmonary artery, esophageal temperature probe, rectal probe).

. Place arterial catheter for invasive blood pressure monitoring and frequent blood sampling. Consider central venous catheter or pulmonary artery catheter if indicated by cardiovascular instability.

. Repeat venous blood gas and electrolytes analysis until these normalize. Repeat creatine kinase at least every 6 hours while the patient is in ICU and then daily until the creatine kinase returns to normal. Assess glucose, clotting function, hepatic and renal functions, and treat symptomatically. Repeat lactic acid measurement after each dantrolene administration.

. Consider hemodialysis if indicated.

. Consider intensive care monitoring for at least 24 hours after malignant hyperthermia episode or after recrudescence of malignant hyperthermia.

. Refer the patient for muscle caffeine-halothane contracture testing and consider exam of *RYR1*. Pursue a pathologic diagnosis for other occult myopathies.

Administer Dantrolene

Dantrolene, a hydantoin with muscle relaxant properties, has greatly changed the treatment of and risk of death from MH. Before the introduction of dantrolene, Brit and Kalow reported a 36% MH survival rate with symptomatic treatment only.[36] Dantrolene decreases both excitation-coupled calcium entry into muscle cells and store-operated calcium entry coupled to RYR1.[7,8] It does not act on the neuromuscular junction or on the passive or active electrical properties of the surface membranes of muscle fibers.

Dantrolene in the formulations Dantrium and Revonto is supplied in 70-mL vials, containing 20 mg of dantrolene sodium and 3 g of mannitol. It must be diluted with 60 mL of sterile, preservative-free, distilled water to produce a clear yellow solution. Dantrolene is also available as Ryanodex, 250 mg of dantrolene with 125 mg mannitol, to which 5 ml of water is added to produce an opaque orange fluid for injection. Dantrolene should be available in all locations where general anesthesia is administered. It should be immediately supplied to other areas of the hospital by the pharmacy. If dantrolene has to be obtained from a central location, such as the pharmacy, it must be stressed that the need for the initial and subsequent doses of drug is urgent. The initial dose of intravenous dantrolene for treatment of MH is 2.5

to 3 mg/kg.[37] More than 10 mg/kg may be required to return metabolism and muscle tone to normal. Dantrolene may irritate veins and if it extravasates it will not be effective in treating MH. Therefore dantrolene should be given through a catheter placed in a central vein if possible. As soon as dantrolene is ordered to treat fulminant MH, the pharmacy should obtain replacements. In children, the intravenous infusion of dantrolene, 2.4 mg/kg IV over 10 to 12 minutes, produced stable blood levels of about 3.5 μg/mL for 4 hours, after which a slow decline in plasma concentration occurred (Fig. 132.1).[38] It appears that the half-life of dantrolene in the plasma of children is somewhat shorter than in adults: 7 to 10 hours compared with 12 hours, respectively.[39] This is consistent with the recommendation to repeat dantrolene (1 mg/kg) every 4 to 6 hours for prophylaxis against recurrence of MH in a child. The goals of treatment with dantrolene are normalization of heart rate, respiratory rate, and muscle tone, correction of hypercarbia, hyperthermia, electrolyte disturbances, and metabolic acidosis. Urinary output should increase and mental status should improve.

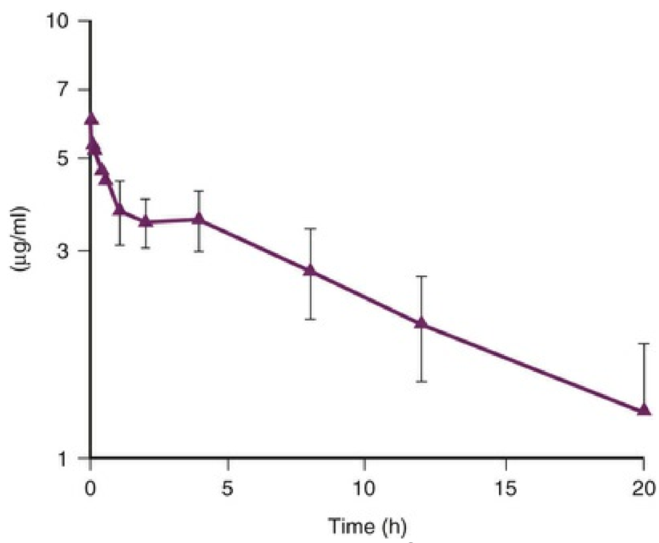

FIG. 132.1 Whole blood concentration of dantrolene versus time in a cohort of children. (Modified from Lerman J, McLeod ME, Strong HA. Pharmacokinetics of intravenous dantrolene in children. Anesthesiology. 1989;70:625.)

The major side effect of dantrolene is muscle weakness, noted in ~25% of patients.[39,40] The effects of dantrolene on strength may persist for more than 8 to 12 hours. It is likely that when the plasma concentration of dantrolene is sufficient to inhibit an episode of MH, the patient will experience weakness and possibly disequilibrium. The ability to swallow could be compromised. Severe muscle weakness of weeks to months in duration can also be the result of an MH episode. Phlebitis is a common side effect of dantrolene administration, noted in approximately 10% of patients.[40]

If no recurrence is noted in the first 24 hours following treatment of MH, the patient is metabolically stable, and weakness is marked, dantrolene administration may be withheld and weaning from supportive therapy begun. If dantrolene must be administered to a patient who is also receiving calcium channel antagonists, invasive hemodynamic monitoring is necessary. Serum potassium should be closely

monitored. Dantrolene may be useful in the treatment of fever and muscle spasticity not associated with MH. Therefore if fever diminishes and abnormal vital signs associated with fever resolve after the administration of dantrolene, the patient did not necessarily have MH.

Symptomatic Treatment

Because respiratory and cardiovascular compromise result from fulminant MH and because the major side effect of dantrolene is muscular weakness, endotracheal intubation and controlled ventilation may be useful. When calculation of O_2 consumption and CO_2 production is simplified by mechanical ventilation, these values serve as the most appropriate monitors of the adequacy of treatment of an episode of fulminant MH. Minute ventilation should be increased several-fold and O_2 provided as needed. When repeated assessment of blood gases indicates resolution of acidosis, minute ventilation can be normalized. Sodium bicarbonate should be administered liberally to treat metabolic acidosis. Low muscle pH may prevent successful treatment of MH.

If the core body temperature is elevated, active measures should be taken to cool the patient. The most effective means of cooling is the intravenous administration of cold normal saline through a peripheral or central vein. The stomach can be lavaged with iced saline. Ice packs may be placed on the groin and the axillae. Wet cloths and a fan can be used to promote surface evaporation. Active cooling should be stopped when core temperature falls below 38.8°C to prevent inadvertent hypothermia.

Cardiac dysrhythmias usually stop when the episode is adequately treated with dantrolene. Lidocaine (1 mg/kg) is recommended for treatment of arrhythmias in MH. Amiodarone (5 mg/kg) can be administered for refractory ventricular tachycardia.[41] Hyperkalemia may require aggressive treatment, especially if arrhythmias have occurred or myoglobinuria has compromised renal function. The administration of calcium gluconate or calcium chloride—and all the other usual treatments to reverse hyperkalemia—is appropriate during the treatment of MH.

Conventional hemodialysis does not remove myoglobin effectively, due to the size of this protein.[42] The use of antioxidants and free radical scavengers such as pentoxifylline, vitamin E, and vitamin C may be justified in the treatment or prevention of myoglobinuric acute renal injury,[43] but more controlled studies are needed. Early hypocalcemia secondary to rhabdomyolysis-induced acute kidney injury should not be treated unless it is symptomatic or severe hyperkalemia is present.[42]

Large losses of intravascular volume may occur, because evaporative loss may be great, edema formation may occur in muscle and other tissues, and mannitol given as part of the formulation of dantrolene may induce significant diuresis. Hypovolemia should be avoided because even mild hypovolemia impairs dissipation of heat produced by increased metabolism.[32] Cardiovascular support, in the form of isotonic fluid administration as well as vasopressor and inotropic drugs (epinephrine, phenylephrine, norepinephrine, dopamine), should be administered as soon as possible if indicated.

The 24/7 MH Hotline is available at 800-644-9737 to lend advice about treating acute MH. This service is supported by MHAUS (www.mhaus.org) and staffed by volunteer anesthesiologists.

Urine and Blood Tests in Malignant Hyperthermia

Myoglobin, a heme-containing respiratory protein, is released from damaged muscle and rapidly excreted in the urine. Myoglobinuria occurs when the renal threshold of 0.5 to 1.5 mg/dL is exceeded. Myoglobinuria is suggested by persistent red to reddish brown urine. At myoglobin levels of 100 mg/dL, urine tests positive for heme by dipstick after centrifugation, whereas the sediment has normal color and tests negative for heme. The dipstick test has a sensitivity of 80% for detection of rhabdomyolysis.[29] Renal injury is frequent when urine myoglobin is more than 1 g/mL. Because the half-life of myoglobin in the plasma is approximately 12 hours, less than the half-life of CK,[44] persistence of myoglobinuria for more than several days suggests that muscle cell integrity continues to be impaired. Patients with chronic myopathies may have moderately raised concentration of plasma myoglobin but not usually overt myoglobinuria.[44] CK increases in the plasma more slowly than myoglobin does. There is no defined threshold value of serum CK above which the risk of acute kidney injury is increased. Usually the risk is low when the CK level is less than 15,000 to 20,000 U/L.[45] With coexisting conditions such as sepsis, dehydration, and acidosis, acute kidney injury may occur with CK values as low as 5000 U/L. After an MH episode, CK should be measured at least daily until stable.

When further evaluation is required to assess for the presence or recurrence of MH, the test most likely to be helpful is venous blood gas analysis. Oxygen desaturation, hypercarbia, and lactic acidemia in mixed venous blood are the results of the hypermetabolism of MH. Elevated $PaCO_2$ is apparent in mixed venous blood before it is abnormal in arterial blood during an episode of MH.[3] There is an increase in lactate release from muscle before a decrease in the partial pressure of oxygen in venous blood during an episode of MH.[46] If venous blood indicates significant acidosis, with $PaCO_2$ greater than 60 mm Hg and bicarbonate less than 19 mEq/L,[3] and the history of the patient is consistent with MH, the physician should assume that the patient is experiencing an episode of MH and treat accordingly with dantrolene.

Course of a Clinical Episode of Malignant Hyperthermia

The case fatality for MH was >70% in the 1970s. Now MH mortality is estimated to be 10-fold less, but deaths continue to occur when succinylcholine is given to hot, stiff patients in the emergency room[47] or when MH is not suspected soon enough in the operating room.[16] The initial clinical signs of an impending episode of MH are nonspecific. The patient's medical history and clinical course usually help to differentiate fulminant MH from other medical, metabolic, or endocrinologic crises such as sepsis, porphyria, thyroid storm,[48] and untreated pheochromocytoma (Box 132.3).[31]

Box 132.3

Differential Diagnosis of Malignant Hyperthermia in the Intensive Care Unit

Neuroleptic malignant syndrome

Exertional hyperthermia and heat stroke

Serotonin syndrome

Sepsis associated with renal and respiratory failure

Central nervous system injury

Postoperative fever

Thyrotoxicosis

Rhabdomyolysis

Pheochromocytoma

Porphyria

Allergic reaction secondary to medications

Blood transfusion reactions

Administration of hypertonic dye such as diatrizoate intrathecally

Drug abuse (cocaine, amphetamines, ecstasy)

Drug withdrawal

Iatrogenic overheating

Delirium tremens

If the triggering agent is removed rapidly, there may be only mild signs suggestive of MH: moderate increases in heart rate, blood pressure, and temperature along with a slight respiratory acidosis. Mild metabolic acidosis and moderate increases in serum myoglobin and CK may or may not be present. Masseter spasm may occur. As previously suggested (see "Clinical Recognition of a Malignant Hyperthermia Episode in Humans"), differentiating an abortive episode of MH from an anesthesia complicated by other factors can be difficult.

Recrudescence

There are cases in which a patient was symptomatically treated for MH with dantrolene, appeared to recover, and then some hours later had another episode of increased metabolic rate. This second episode was sometimes accompanied by remarkable stiffness of the muscles. Recrudescence of MH was reported in 20% of cases reported to the MH Registry[49] after initial treatment appeared to be successful. Muscular body type, the presence of temperature increase during the MH episode, and a longer time between the induction of inhalation anesthesia and the first sign of

MH were associated with a greater risk of recrudescence.[49] There is no definite or guaranteed time course for these events in the human. Observation of the patient rescued from an MH event closely for 24 hours will allow for the early recognition and treatment of recrudescence. Such patients should be monitored in an ICU setting because of the utility of invasive cardiovascular monitoring in documenting the course of an episode of MH. Recrudescence of MH can progress into fulminant MH and therefore warrants aggressive treatment with dantrolene and supportive therapy.

Factors That Trigger Malignant Hyperthermia

Potent inhalational anesthetic agents such as sevoflurane, halothane, enflurane, isoflurane, and desflurane have been identified as triggering agents of MH in humans. Depolarizing neuromuscular blocking agents are also potent triggers of MH in humans. Succinylcholine is the only drug of this type currently in common use. Different anesthetics may trigger MH at different rates depending on the combination of agents used. The combination of succinylcholine and potent inhalation anesthetic agents produces more episodes of MH than do potent inhalation anesthetic agents administered without succinylcholine or succinylcholine administered in the presence of nitrous oxide and intravenous anesthetic agents.[22,23] A number of drugs, such as amide local anesthetics, droperidol, ketamine, calcium, digitalis, methylxanthines, anticholinergics, anticholinesterases, and sympathomimetic drugs, had in the past been considered to be potential triggers of MH in humans, primarily on theoretic grounds. Review of clinical and laboratory[50,51] experience suggests that these drugs are not triggers of MH. However, on rare occasions, MH may occur during an anesthesia in which no trigger agents were administered or without exposure to any anesthetic.[52] This is rare in humans but has been observed repeatedly in MH-susceptible animals.[53] An athletic adolescent who had an *RYR1* mutation associated with MH died after strenuous exercise.[54]

Muscular Diseases and Malignant Hyperthermia

There are a few relatively rare muscular diseases that are closely linked with MH susceptibility. These include central core disease, multiminicore and nemaline rod myopathies,[55] and King-Denborough syndrome.[56] Central core disease (CCD) is a congenital myopathy, characterized by motor developmental delay and signs of mild proximal weakness, most pronounced in the hip and girdle musculature. A patient with dystrophinopathy (Duchenne or Becker muscular dystrophy) can develop a hyperkalemic cardiac arrest and exacerbation of rhabdomyolysis after administration of the potent inhalation anesthetic agents, but this is not an MH episode. During initial treatment, such cases can be difficult to differentiate clinically from MH. Indeed, calcium is not handled normally in dystrophic muscle, and RYR1 channels are abnormal.[58] In the presence of neuromuscular disease, myoglobinuria may occur after exposure to potent inhalation anesthetics alone[44,59] and is to be expected after succinylcholine administration in patients with muscular dystrophy.[44] A child with myopathy who receives potent inhalation anesthetic agents can develop an increase in postoperative serum CK and potassium concentrations as well as myoglobinuria. These findings are due to the myopathy, not to MH.

Myotonias are a class of inherited skeletal muscle diseases characterized by impaired relaxation after sudden voluntary muscle contraction. There are defects in the chloride, sodium, and calcium channels in the different types of myotonia. In the presence of myotonia the risk for MH is not greater than that of the general population, with the possible exception of hypokalemic periodic paralysis. Many cases of hypokalemic periodic paralysis are associated with variants in the *CACNA1S*, which codes for the DHPR, the voltage gate of the RYR1. Thus there is a theoretic association between MH and hypokalemic periodic paralysis, which has not been clearly confirmed.[11] To prevent episodes of myotonic contractures, depolarizing neuromuscular blocking agents such as succinylcholine should not be given to patients with myotonia. Other details of preventive management may differ between different forms of myotonia. In general myotonic patients should be maintained in a normothermic state, episodes of anxiety should be avoided, and serum potassium should be documented. If nondepolarizing neuromuscular blocking agents (NMBAs) must be used, a drug with short duration is best and neuromuscular function should be monitored. The use of anticholinesterase drugs has been reported to precipitate myotonia. Neither nondepolarizing NMBAs nor dantrolene will counteract myotonic rigidity. Lidocaine, a sodium channel blocker, may decrease myotonic rigidity.

Patients with mitochondrial disease may develop acidosis, fever, and rhabdomyolysis. All anesthetics depress mitochondrial function, but there is no clear relationship between MH and mitochondrial myopathy.

Heat Illness and Malignant Hyperthermia Susceptibility

Exertional heat illness (EHI), exertional rhabdomyolysis (ER), and MH are all hypermetabolic states and can have similar manifestations. EHI is caused by excessive heat production with insufficient heat dissipation. It can progress to exertional heat stroke (EHS), which includes extreme hyperthermia (core body temperature higher than 40°C or 104°F) associated with central nervous abnormalities (delirium, coma, seizure). EHS can progress to multiorgan failure[60] with rhabdomyolysis. The CHCT can confirm the diagnosis of MHS, but it cannot be used to diagnose the potential for EHI or ER. Because there is a subset of patients who present with heat stroke and are also susceptible to MH, Grogan and Hopkins[61] suggested that EHI patients undergo testing for MH susceptibility. However, the majority of ER and EHS cases do not have a subclinical myopathy such as MH susceptibility.[61,62]

Evaluation of Patients at Risk

The most efficient way to evaluate a family for MHS is to first evaluate the index patient with a contracture test (CHCT) of living muscle.[63] Many individuals suspected of experiencing MH may have normal CHCT results. This is the only method that can confirm the diagnosis of *not* MHS. CK levels, at rest, are of no predictive value in the general population.[64,65] In some populations, more than 25% of the patients with elevated CK levels were not susceptible to MH on CHCT testing.[66] However, if a relative of an MHS patient with chronic CK elevation has elevated CK, that individual is likely to be MHS also.[65]

Testing for Malignant Hyperthermia Susceptibility

In Vitro Caffeine-Halothane Contracture Testing

In vitro caffeine-halothane contracture testing (CHCT) is the only specific lab test of MH susceptibility other than identification of a *RYR1* mutation. At least 2 to 3 months should pass between an episode of suspected MH and the date of muscle biopsy for CHCT.[67] This test has been described in detail, and the standards for its performance have been accepted by the specialized centers in North America[68] and Europe[58] that perform it. The addresses of centers where muscle biopsy and contracture testing can be done can be found at www.mhaus.org and www.emhg.org. CHCT has a sensitivity of 97% and a specificity of 78%.[69] It was designed to decrease the rate of false negatives. Therefore it may produce false-positive results. A video of this procedure can be seen at www.mhaus.org. The negative predictive value of CHCT is high, but because the specificity of the in vitro test is only 85% at best, the positive predictive value of this test varies greatly depending on the prior probability of the individual being susceptible to MH.[70] As much clinical and laboratory evidence as can be obtained regarding the MH event should be used to interpret the results of CHCT. Genetic analysis may be helpful if several generations of one family can be examined.

Less Invasive Tests of Malignant Hyperthermia Susceptibility

None of the relatively noninvasive tests of MH susceptibility have proved as sensitive and as specific as the in vitro caffeine-halothane contracture test. Tests that have been evaluated in the past include calcium uptake into frozen muscle, skinned fiber testing, platelet nucleotide depletion, ionized calcium concentration in lymphocytes, force of contracture, and phosphorus nuclear magnetic resonance spectroscopy. Other tests based on RYR1 function in lymphocytes,[71,72] pharmacologic response in muscle cell cultures,[73-75] and microdialysis study of in situ muscle[76] have been proposed. None of these are usefully clinically thus far.

An alternate to the caffeine-halothane contracture test for confirmation of MH susceptibility is a genetic test of *RYR1*. This was developed from genetic analysis of families in which many individuals had undergone muscle contracture tests. Patients who had strong contracture test results underwent characterization of *RYR1*. The exons in which variants are most commonly found were studied first (the hot spots). Variant tissues were studied in vitro to confirm that they altered calcium in a manner consistent with causing MH. At present, more than 300 *RYR1* variants have been documented; of these, only 34 have been formally accepted as causative MH mutations (see www.emhg.org). Therefore the sensitivity of the clinical *RYR1* exam, which sequences only the exons in which known causative MH mutations are located, is at best 30%. Sequencing of the entire *RYR1* gene may detect a variant in 50% to 70% of people who would have positive CHCT results. However, it is difficult to interpret the medical implications of the variants of unknown significance that may be identified. Professional genetic counseling is appropriate, in concert with consultation with a neurologist, when genetic testing of MH susceptibility is

considered. Genetic testing has been useful postmortem when the clinical circumstances were consistent with fulminant MH.[16] Addresses of the genetic laboratories can be found at www.mhaus.org. Patients with strong contractures in the presence of 3% halothane and no findings on *RYR1* may have a defect in a different protein. If *RYR1, CACAN1S,* and *stac3* sequencing fail to identify an MH-causative mutation, that patient should undergo muscle contracture testing to further evaluate MH susceptibility. A normal result on the CHCT is the only method that can currently prove that an individual is not MH susceptible.

Neuroleptic Malignant Syndrome and Serotonin Syndrome

Neuroleptic malignant syndrome (NMS) can be fatal. It develops insidiously over days. Initial signs include changes in mental status and extrapyramidal function. Sinus tachycardia or oscillation of blood pressure is common. Muscle rigidity that can be described as "lead pipe," hyperthermia, and increased CK are major manifestations of NMS. Renal failure due to rhabdomyolysis and respiratory distress are serious complications of NMS.

NMS has been reported within 7 days after the administration of antipsychotic drugs given to treat psychiatric disorders. NMS may occur 2 to 4 weeks after the administration of depot neuroleptics and days after the intravenous administration of various antipsychotic and antiemetic medications of the phenothiazine and butyrophenone classes.[77] Surgical patients may have received neuroleptics as antiemetics or sedatives. NMS can occur at any age. Silva and associates,[78] reviewing the literature on NMS in children, found 77 cases in patients of less than 1 to 18 years, with only 10 patients younger than 10 years of age.

The treatment of NMS starts with the discontinuation of neuroleptic agents as well as the institution of supportive treatment to control hyperthermia, sustain vital functions, and prevent renal failure. There is evidence that NMS results from an acute reduction in dopaminergic function in the brain. Medications such as amantadine, bromocriptine, and levodopa have been used in treatment of NMS. Dantrolene, which inhibits muscle contraction and heat production, was reported to be effective in 81% of patients with NMS.[79] Electroconvulsive therapy (ECT) has also been suggested to be therapeutic.

The potential for susceptibility or cross-reactivity to both MH and NMS in the same patient is unproved. However, five of seven NMS patients who underwent muscle biopsy for in vitro halothane contracture testing had significantly abnormal results. Therefore the recommendation has been made to treat NMS patients as MH susceptible until proved otherwise. Unfortunately, this can pose anesthetic difficulties during ECT. Succinylcholine, a potent trigger of MH, is a useful drug for lessening the force of the convulsions that accompany ECT. One patient who had experienced NMS did later receive succinylcholine repeatedly for ECT without complications.[80] Therefore it is unclear whether patients who have had NMS should be prevented from receiving anesthetic agents capable of triggering MH when these drugs are otherwise indicated. On the other hand, neuroleptic agents have been considered safe to administer to MHS patients, but there is some risk of hyperthermic reactions.[81]

There is evidence that patients with proximal myotonic dystrophy may be at increased risk for muscular complications after receiving neuroleptic drugs. Schneider and associates described a patient with this disease who developed muscle stiffness, oculogyric dystonias, and elevated CK after administration of a neuroleptic. This patient had a positive contracture test for MH susceptibility.[81]

Serotonin syndrome (SS) is another potentially life-threatening condition associated with increased serotonergic activity in the central nervous system, as a result of stimulation of postsynaptic 5-HT_{1A} and 5-HT_{2A} receptors.[82] It may result from any combination of drugs that increase serotonergic activity, such as amphetamine, cocaine, selective serotonin reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, triptans, lithium, dextromethorphan, and ondansetron. The diagnosis of SS in the pediatric population can be difficult. Clinical manifestations include autonomic changes such as tachycardia, hyperthermia, hypertension, diaphoresis, and diarrhea and increased neuromuscular activity with tremor, muscle rigidity, hyperreflexia, and clonus. In SS, neuromuscular findings are typically more pronounced in the lower extremity,[83] compared with MH where there is a rigor-mortis–like rigidity. When compared with NMS, the distinguishing features of SS, besides the different causative agents, are a rapid onset (within 24 hours),[83] hyperreactivity (tremor, clonus, increase in reflexes), and rapid resolution.[82] See www.mhaus.org/nmsis for a website devoted to neuroleptic malignant syndrome and similar disorders.

Although there may be similarities in the presentation of MH, NMS, and SS, they have pathophysiologic differences. Nevertheless, there is experimental evidence in animals that stress-induced MH, more than anesthetic-induced MH, may be mediated in part by 5-HT.[84]

Malignant Hyperthermia Association

The Malignant Hyperthermia Association of the United States is a valuable resource for families affected by MH, NMS, or SS and for their physicians. This organization offers information, expert consultation, and referral. MHAUS maintains a 24-hour, professionally staffed telephone line to assist physicians and patients in dealing with MH (1-800-644-9737). All cases of suspected MH and similar heat-related disorders should be reported to the North American Malignant Hyperthermia Registry (telephone, 888-274-7899; website, www.mhaus.org/registry) to support the continued epidemiologic study of MH.

CHAPTER 133

Neuromuscular Blocking Agents

Joseph D. Tobias

PEARLS

- Through the blockade of skeletal muscle function, neuromuscular blocking agents (NMBAs) cause cessation of respiratory function, mandating airway control and the institution of mechanical ventilation. The inability to manage the airway with the provision of bag-mask ventilation and endotracheal intubation will result in hypoxemia and death. NMBAs should not be administered if there is any question as to the normalcy of the airway and the ability to successfully accomplish bag-valve-mask ventilation.
- The term *NMBA* rather than muscle relaxant may be preferable as the latter seems to imply some implicit type of sedative or relaxant property that these agents do not possess. As such, use of the term *NMBA* identifies in their name their mechanism of action, further emphasizing that they are devoid of sedative or analgesic properties.
- NMBAs can broadly be divided into two separate classes on the basis of their mechanism of action. Depolarizing agents such as succinylcholine mimic the action of acetylcholine at the neuromuscular junction and activate or depolarize the muscle, whereas nondepolarizing agents such as pancuronium or rocuronium act as a competitive antagonist to the effects of acetylcholine at the neuromuscular junction, thereby blocking its effects.

Introduction

In the pediatric ICU (PICU) setting, there may be circumstances in which prevention of movement is necessary, thereby mandating the use of neuromuscular blocking agents (NMBAs) (Table 133.1).[1] Although these agents can be used as a single dose to facilitate brief procedures such as endotracheal intubation, prolonged administration may be necessary in specific clinical scenarios. With an improved understanding of the techniques for providing sedation and analgesia in the PICU setting and data demonstrating not only their adverse effect profile but also their lack of efficacy in

specific clinical scenarios, there has been a decrease in the prolonged administration of NMBAs.[2] A past survey from the PICU setting suggests that the prolonged administration of these agents is used most commonly as an adjunct in the control of intracranial pressure (ICP), although the recent resurgence in the use of hypothermia following cardiac arrest and cerebral ischemia has seen the increased use of these agents to prevent shiveriing.[3-5]

TABLE 133.1

Reported Indications for Neuromuscular Blockade in the Pediatric ICU

Facilitation of procedures or diagnostic studies:
______endotracheal intubation
______central line placement
______radiologic imaging (MRI, CT scanning)
Immobilization during interhospital or intrahospital transport
Intensive care indications:
______facilitate mechanical ventilation
______control increased intracranial pressure
______eliminate shivering (especially during therapeutic hypothermia)
______decrease peripheral oxygen utilization
______control severe agitation unresponsive to adequate sedation
______maintain immobilization after surgical procedures
______decrease the risk of pulmonary vasospasm in patients with pulmonary hypertension
______manage patients with tetanus

Given their adverse effect profile including the potential for increased nosocomial infections, longer duration of mechanical ventilation, and pressure injuries, NMBAs should be used only when absolutely indicated, by personnel with appropriate training in their pharmacology, and only after obtaining the knowledge and skills needed to treat adverse effects related to their use. Use of the terminology “muscle relaxant” should be avoided as this seems to imply some implicit sedative property, which these agents do not possess. Because these agents provide no amnestic, analgesic, or sedative properties, coadministration of an amnestic agent (ie, benzodiazepine, ketamine, propofol, or a barbiturate) is necessary whenever they are used. The term *NMBA* is preferred because it identifies the mechanism of action of these agents as a competitive antagonist for acetylcholine at the neuromuscular junction.

Following the administration of an NMBA and the blockade of skeletal muscle function, cessation of ventilation with apnea mandates airway control, endotracheal intubation, and the institution of mechanical ventilation. The inability to manage the airway including the provision of bag-valve-mask ventilation and endotracheal intubation will result in the potential for hypoxemia and death. As such, before these agents are used for endotracheal intubation, the normalcy of the airway and ability to provide bag-valve-mask ventilation and endotracheal intubation should be

assessed.[6,7] If problems managing the airway are anticipated, NMBAs should not be administered. Furthermore, when using these medications, one should be familiar with the "cannot intubate–cannot ventilate" algorithm and have ready access to the needed equipment for rescue in this scenario.[7]

Neuromuscular Junction

Normal neuromuscular transmission results from the release of acetylcholine from the nerve terminal, its movement across the synaptic cleft, and binding to the postsynaptic nicotinic receptor on the sarcolemma of the skeletal muscle. Acetylcholine is synthesized in the cytoplasm from acetyl coenzyme A and choline and stored in synaptic vesicles in the axonal terminals of the presynaptic membrane. Depolarization of the presynaptic axonal membrane opens calcium channels (P channel). The movement of calcium through the channels in the presynaptic membrane results in the movement of synaptic vesicles, which hold acetylcholine, toward the membrane, their fusion with the membrane, and the release of acetylcholine into the synaptic cleft. The P channel can be blocked by cations such as magnesium and lithium but generally not by calcium channel antagonists. The concurrent administration of magnesium or lithium potentiates the effect of nondepolarizing NMBAs. The excessive administration of either cation can have significant effects on normal neuromuscular function and cause muscle weakness. After its release from the synaptic vesicles, acetylcholine diffuses across the synaptic cleft and binds to acetylcholine receptors on the postsynaptic membrane (sarcolemma).

The acetylcholine receptor (nicotinic receptor on the sarcolemma) is a pentameric protein composed of five subunits. There are five possible subunits (alpha, beta, gamma, delta, and epsilon), each of which is encoded by a different gene. The normal acetylcholine receptor found in adults includes two alpha subunits combined with one each of the beta, delta, and epsilon subunits. Binding of an acetylcholine molecule to each of the two alpha subunits is necessary for opening of the channel and depolarization of the sarcolemma. During various stages of development or in pathologic disease states, the composition of the acetylcholine receptor may change. Immature and denervated acetylcholine receptors have a gamma subunit instead of the epsilon, while a demyelinated neuromuscular junction contains acetylcholine receptors composed of a pentamer of alpha subunits. The importance of these variants is that their response (opening of the ion channel) may be dramatically different from the normal adult variant of the acetylcholine receptor. These differences can have devastating consequences following the administration of succinylcholine. The channel may remain open for a prolonged period of time, resulting in the release of intracellular potassium. The acetylcholine receptor occupies the entire membrane from the outside of the muscle through the cell membrane to the inside and thereby regulates the transmembrane movement of ions. The receptor acts to convert the chemical stimulus (acetylcholine) into an electrical impulse that results in the depolarization of the sarcolemma. The depolarization of the sarcolemma results in the release of calcium from the sarcoplasmic reticulum (SR) and muscle contraction.

Stimulation of the acetylcholine receptor opens ion channels allowing the movement of small, positively charged cations such as sodium, potassium, and

calcium. The sodium influx depolarizes the muscle membrane leading to the release of calcium from the SR and muscle contraction. Cessation of muscle contraction and repolarization occurs when acetylcholine is metabolized by the enzyme acetylcholinesterase, which is present in the synaptic cleft. This repolarization resets the muscle for the next round of depolarization and excitation-contraction coupling. Failure to metabolize acetylcholine bound to the receptor results in prolonged depolarization, inability to repolarize the sarcolemma, and cessation of further contraction.

Neuromuscular Blocking Agents: Depolarizing Agents

The two general classes of NMBAs (depolarizing and nondepolarizing agents) differ in their basic mechanism of action. Depolarizing agents such as succinylcholine (suxamethonium in Europe and the United Kingdom) mimic acetylcholine, binding to the acetylcholine receptor at the neuromuscular junction and activating it. As succinylcholine is resistant to degradation by acetylcholinesterase, there is sustained occupation of the receptor and failure of repolarization, which results in neuromuscular blockade. This action of succinylcholine accounts for the clinical effects that are seen including the initial muscle fasciculations followed by flaccid paralysis lasting 5 to 10 minutes, the time necessary for the degradation of succinylcholine by pseudocholinesterase and subsequent repolarization of the sarcolemma. The onset of action of succinylcholine is more rapid than any of the nondepolarizing agents with neuromuscular blockade, occurring in 30 to 45 seconds, thereby allowing for rapid control of the airway with endotracheal intubation. Additionally, many of the studies comparing succinylcholine to nondepolarizing NMBAs suggest it produces better conditions for endotracheal intubation.[8]

Succinylcholine undergoes rapid redistribution and metabolism by the plasma enzyme, pseudocholinesterase (butyrylcholinesterase), which limits its clinical duration to 5 to 10 minutes. In some patients, a congenital or acquired deficiency of pseudocholinesterase prolongs duration of action. When considering such scenarios, there may be issues with the total amount of enzyme (quantitative defect) or efficacy of the enzyme (qualitative defect).[9] Decreased enzyme levels (quantitative defects) are usually acquired while qualitative issues are inherited. The inherited form of pseudocholinesterase deficiency, resulting in a qualitative defect in the enzyme, is an autosomal recessive trait with an incidence of 1 : 2500 to 3500. Only homozygotes have a clinically significant prolongation of the effect of succinylcholine with neuromuscular blockade lasting up to 4 to 8 hours following a routine dose of succinylcholine (1–2 mg/kg). Disease states that lead to a quantitative decrease in pseudocholinesterase levels include severe liver disease, myxedema, pregnancy, protein-calorie malnutrition, and certain malignancies. Drugs and medications can also affect pseudocholinesterase levels including chemotherapeutic agents, such as cyclophosphamide and echothiopate ophthalmic drops. Deficiency can also result from the recent use of plasmapheresis as the enzyme is removed with the plasma. With either qualitative or quantitative defects of pseudocholinesterase, suspicion should be aroused if there is failure of the return of the train-of-four (TOF) with peripheral nerve stimulation (see later). Although such problems are rare, it is

prudent to demonstrate the return of neuromuscular function following the administration of succinylcholine and prior to the administration of a nondepolarizing agent. This can be accomplished by demonstrating the return of the TOF after succinylcholine is administered. If such a problem is suspected, the primary therapy includes continuation of ventilatory support until the patient's muscle strength returns and the provision of amnesia with an anesthetic agent (benzodiazepine, propofol, continuing a volatile anesthetic agent). While movement is prevented, the patient will be aware and awake once the effect of these agents has stopped. The enzyme plasma cholinesterase is contained in fresh frozen plasma (FFP); however, due to the infectious disease concerns with the use of blood products, reversal with the administration of FFP cannot be recommended.[10-12] Purified human plasma cholinesterase has also been used; however, such a practice is expensive and is not available in most centers.[13]

Despite its rapid onset and rapid offset, the potential adverse effects associated with succinylcholine can be devastating and even fatal (Table 133.2). Direct effects on cardiac rhythm have been reported including bradycardia, tachycardia, and atrial or ventricular ectopy.[14] Succinylcholine has a chemical structure resembling that of acetylcholine and may thereby result in bradycardia from activation of cardiac muscarinic receptors. Bradycardia may be more common in several specific clinical scenarios and situations including (1) infants and children, (2) during halothane anesthesia, (3) in the presence of hypoxemia, (4) with IV as compared with IM administration, (5) when succinylcholine is administered concurrently with other medications that have negative chronotropic effects (propofol, fentanyl), (6) in the presence of hypothermia, (7) in patients with increased intracranial pressure (ICP), or (8) with repeated dosing. The latter may occur during difficulties with endotracheal intubation when the first dose is wearing off. In these populations or scenarios, succinylcholine should always be preceded by an anticholinergic agent such as atropine. Arrhythmias, although fairly common, occurring in up to 50% of patients following the administration of succinylcholine, are generally short-lived and of limited clinical significance. The use of an anticholinergic agent will decrease but not eliminate the incidence of arrhythmias. As with the potential for bradycardia, arrhythmias tend to be more common with repeated doses of succinylcholine.

TABLE 133.2

Adverse Effects of Succinylcholine

Prolonged blockade with acquired or inherited pseudocholinesterase deficiency
Cardiac arrhythmias:
______bradycardia
______tachycardia
______asystole
______atrial and ventricular ectopy
Hypertension
Increased intraocular pressure
Increased intragastric pressure

Increased intracranial pressure
Diffuse myalgias
Myoglobinuria
Malignant hyperthermia
Hyperkalemia (see Table 133.3)

As succinylcholine activates the acetylcholine receptor before producing neuromuscular blockade, depolarization of the muscle end plate occurs with contraction of the muscle fascicles or fasciculations. These fasciculations are responsible for the myalgias that may occur following succinylcholine.[15] Although not a primary concern when succinylcholine is used for emergently securing the airway, the use of succinylcholine may not be optimal for facilitating endotracheal intubation for outpatient surgery when such issues may interfere with activities of daily living and return to work. One advantage of fasciculations is that their cessation signals that neuromuscular blockade is complete and one can proceed with direct laryngoscopy and tracheal intubation. The severity of the fasciculations can be prevented by the administration of a small dose of a nondepolarizing agent, generally 1/10th of the dose normally used for endotracheal intubation (curare 0.03–0.05 mg/kg, rocuronium 0.05 mg/kg, or pancuronium 0.01 mg/kg) before succinylcholine.[16] This is referred to as a "defasciculating dose." The technique is commonly used in the operating room as a means of preventing or attenuating the postoperative myalgias when succinylcholine is administered to adults.

Defasciculation is not commonly used in the pediatric population for several reasons: (1) children younger than 6 years of age do not fasciculate; (2) the use of the defasciculating dose delays the onset of paralysis and increases the dose of succinylcholine needed; (3) in patients with severe respiratory or hemodynamic compromise, the defasciculating dose can cause a significant degree of neuromuscular blockade leading to respiratory insufficiency or laryngeal incompetency with the risk of aspiration; and (4) full efficacy may require up to 2 to 3 minutes, thereby making the technique less optimal when emergent securing of the airway is necessary. If a defasciculating dose is used in patients who are awake and coherent, they should be warned that they may feel the effects of the medication, with the development of diplopia related to the effects of the drug on the extraocular muscles. Additionally, some patients may feel the effects on the muscles of ventilation, resulting in complaints of shortness of breath or dyspnea.

In addition to myalgias, the fasciculations caused by succinylcholine may result in a transient increase in plasma creatinine phosphokinase (CPK) and myoglobin levels. Myoglobinemia has been reported in up to 40% of patients when there is the concomitant administration of general anesthesia with halothane. In these patients, levels high enough to result in myoglobinuria have been reported in 8% of patients.[17] The rise in plasma CPK and myoglobin levels does not occur with IM administration and may be attenuated by the administration of a defasciculating dose (see earlier). These effects should be differentiated from the potentially lethal complications of rhabdomyolysis, which may occur in patients with specific disorders of the neuromuscular junction and malignant hyperthermia (see later). These latter disorders absolutely contraindicate the use of succinylcholine.

The fasciculations may also lead to an increase in intragastric (IGP) and intraocular pressure (IOP). The transient and minimal rise in IGP is generally of limited clinical significance and does not increase the risk of vomiting or passive regurgitation during endotracheal intubation. In the emergency setting, when succinylcholine is chosen for endotracheal intubation, rapid sequence intubation will be used with the application of cricoid pressure to protect against acid aspiration. The contraction of extraocular muscles leads to an increase of IOP following the administration of succinylcholine. The increase is transient with a return of the IOP to baseline within 5 to 8 minutes. Given this effect, the administration of succinylcholine to patients with an open globe injury is generally contraindicated due to the theoretical risk of causing extrusion of the intraocular contents.[18] In settings with an open globe where the use of succinylcholine is considered warranted on the basis of the patient's status, various medications including dexmedetomidine have been shown to blunt the increase in IOP.[19,20]

The effects of succinylcholine on ICP and its use in patients with altered intracranial compliance remain controversial. Succinylcholine may result in a mild to modest ICP increase through various postulated mechanisms including muscle fasciculations and increased venous tone, as well as a direct cholinergic mechanism due to activation of muscle spindles in the peripheral skeletal musculature.[21] Succinylcholine's effects on muscle spindles have also been postulated to cause CNS activation and dreaming during general anesthesia.[22] The dreaming has not been associated with awareness or recall. The effects on ICP are generally mild and transient.

Given its rapid onset (30 to 45 seconds), succinylcholine allows for rapid endotracheal intubation and control of arterial oxygenation and ventilation. As the latter are primary determinants of ICP, any mild increase due to the direct effects of succinylcholine is rapidly controlled. The authors of a recent review article evaluating the evidence-based medicine regarding succinylcholine and ICP concluded: “There is insufficient evidence that administration of suxamethonium causes an increase in intracranial pressure when administered to patients with traumatic brain injury. Further adequately powered studies are required to assess such a relationship. Until such evidence exists, the superior intubation conditions created by suxamethonium in comparison with rocuronium mean that suxamethonium should remain the first choice agent for neuromuscular blockade as part of a rapid sequence induction in head-injured patients unless absolute contraindications to suxamethonium use exist.”[23]

Succinylcholine can also cause a transient increase in the tone of the masseter muscles. The incidence of this problem is significantly higher in the perioperative setting when succinylcholine is administered with the volatile anesthetic agent halothane. A defasciculating dose of a nondepolarizing agent may abolish this phenomenon. This effect may be seen in all of the peripheral skeletal musculature but is accentuated in the masseter muscles, resulting in what is clinically known as masseter spasm. The effect is generally mild and can be overcome by manual opening of the mouth.[24] In rare circumstances, the masseter spasm may be severe, preventing mouth opening and precluding standard oral endotracheal intubation. It has been suggested that patients who manifest masseter spasm to this degree are at risk for malignant hyperthermia (MH), a rare inherited disorder of muscle metabolism that, if untreated, is generally fatal (see later). The data regarding the

relationship between masseter spasm and MH are conflicting. In a prospective evaluation with monitoring of masseter muscle tone, patients who developed significant increases in masseter muscle tone did not proceed to develop MH.[25] However, retrospective series have suggested that the development of masseter spasm may be a prelude to MH, thereby clouding the issue as to how to deal with such patients.[26] In the emergency situation, should patients develop masseter spasm following the administration of succinylcholine, they must be monitored for signs of MH including hypercarbia, hyperthermia, tachycardia, and rhabdomyolysis with myoglobinuria. Treatment with dantrolene is suggested should there be a concern regarding the development of MH (see later).

The major concerns with succinylcholine are its potential to trigger MH and its ability to cause massive hyperkalemia if administered to patients with various comorbid disease processes.[27] MH is an inherited disorder (autosomal dominant) of muscle metabolism with abnormalities of the ryanodine receptor (the calcium release channel of the sarcoplasmic reticulum of skeletal muscle). The point mutation of the ryanodine receptor leads to ongoing release of calcium and therefore sustained muscle contraction following exposure to succinylcholine or a potent inhalational anesthetic agent. During MH, ongoing muscle contraction and metabolism lead to hyperthermia, acidosis, tachycardia, hypercarbia, and rhabdomyolysis with secondary hyperkalemia. Treatment includes discontinuation of the triggering agent, treatment of hyperthermia and the biochemical derangements including acidosis and hyperkalemia, and administration of dantrolene, which blocks ongoing calcium release from the sarcoplasmic reticulum. Therefore in clinical scenarios where succinylcholine may be administered, ready access to dantrolene is recommended.

Lethal hyperkalemia following succinylcholine may occur in patients with certain underlying disorders or comorbid diseases (Table 133.3).[27] Although many of the disorders listed in Table 133.3 are readily apparent, such as the muscular dystrophies, the occurrence of cardiac arrest following succinylcholine administration to apparently healthy children led to a restructuring of the package insert and recommendations for the use of succinylcholine. Children with muscular dystrophy may not manifest symptoms until they are 4 to 6 years of age. If succinylcholine is administered during routine anesthetic care or other clinical scenarios, lethal hyperkalemia can occur. Because of such problems, the current recommendations are that succinylcholine be used only for emergency airway management when rapid sequence endotracheal intubation is necessary, when there is a concern about the ability to provide endotracheal intubation (potentially or documented difficult airway), or when intramuscular administration is necessary because IV access cannot be secured. Also of concern in the pediatric population are patients with relatively rare genetic, chromosomal, or metabolic defects in whom the effects of succinylcholine have not been fully evaluated. Given the rarity of such syndromes, there is limited evidence-based medicine on which to provide recommendations regarding the safety of succinylcholine use. In such settings, the risk-benefit ratio should be examined. In many of these patients, the use of a rapidly acting, nondepolarizing agent may be the better option. The safety of succinylcholine use with minimal increases in serum potassium concentrations has been demonstrated in children with cerebral palsy, as well as those with meningomyelocele.[28-30] Regardless of the clinical scenario, if problems occur following the administration of succinylcholine, hyperkalemia should be suspected

and the resuscitation tailored accordingly.

TABLE 133.3 **Conditions Associated With Hyperkalemia After Succinylcholine Administration**
Preexisting hyperkalemia
Muscular dystrophy
Burns after 48 h involving >10%-15% body surface area
Profound metabolic acidosis
Paraplegia or quadriplegia
Denervation injury
Metastatic rhabdomyosarcoma
Parkinson disease
Disuse atrophy or prolonged bedrest
Polyneuropathy
Degenerative central nervous system disorders
Purpura fulminans
Tetanus
Guillain-Barré
Myotonia dystrophy
Prolonged administration of nondepolarizing neuromuscular blocking agent

In emergency situations when IV access cannot be readily obtained, succinylcholine can be administered intramuscularly in a dose of 4 to 5 mg/kg. IM administration will result in neuromuscular blockade sufficient to allow for endotracheal intubation in 2 to 3 minutes and will rapidly (<30 seconds) treat laryngospasm occurring during anesthetic induction when IV access is not available, thereby allowing for effective bag-valve-mask ventilation. Use of the IM route for the administration of succinylcholine is most commonly chosen intraoperatively during the inhalation induction of anesthetic when IV access is not present.[31] In this scenario, succinylcholine should be administered into the deltoid muscle as the onset times are more rapid than with administration into the quadriceps. Alternatively, administration into the tongue or the submental space has been suggested as blood flow to this area is generally well maintained even when peripheral vasoconstriction has occurred.[32] Unlike IV administration, there is limited risk of bradycardia with IM administration.[33] The IM route is not recommended in patients with conditions that decrease cardiac output or blood flow to the muscles, such as shock or bradycardia, as the onset of action will be significantly delayed. Given these concerns, IM administration is generally not recommended in critically ill children and intraosseous administration (1–2 mg/kg) is preferable when IV access is not available.[34,35]

Currently, the package insert and good clinical practice allow for administration of succinylcholine when there may be a potentially difficult airway, in the emergency

situation when rapid securing of the airway is necessary (full stomach when a rapid sequence intubation is performed), and when there is no IV access (IM administration), provided that there is no contraindication to its use (Table 133.3).[27] When dealing with the potentially difficult airway or unrecognized difficult airway, the major advantage of succinylcholine is that there should be return of normal neuromuscular function within 10 minutes as opposed to 60 minutes following a 1-mg/kg intubating dose of rocuronium (see later). For IV administration, clinically used dosing recommendations for succinylcholine vary from 1 to 2 mg/kg.[36] Larger doses are likely not to improve intubating conditions while slightly prolonging the duration of action.

Neuromuscular Blocking Agents: Nondepolarizing Agents

Nondepolarizing NMBAs function as competitive antagonists at the neuromuscular junction, antagonizing the effects of acetylcholine at the receptor. Unlike succinylcholine, these agents do not activate the acetylcholine receptor and therefore do not result in fasciculations and the associated problems that may occur (see earlier). Nondepolarizing NMBAs are used most commonly intraoperatively to facilitate endotracheal intubation and also to provide ongoing muscle relaxation for specific surgical procedures such as exploratory laparotomy. When used to provide ongoing neuromuscular blockade in the operating room or ICU, these agents can be administered by intermittent bolus dosing or continuous infusions. There are two basic chemical structures of the nondepolarizing NMBAs available for clinical use: aminosteroid and benzylisoquinolinium compounds (Table 133.4). The difference in their chemical structure has limited clinical significance. Of more importance are differences in onset, duration of action, cardiovascular effects, metabolism, metabolic products, and cost. These principles are reviewed in the remainder of this chapter.

TABLE 133.4
Classification of Nondepolarizing Neuromuscular Blocking Agents

Aminosteroid compounds:
______pancuronium
______rocuronium
______vecuronium
______pipecuronium
______rapacuronium (no longer available)
Benzylisoquinolinium compounds:
______mivacurium
______atracurium
______cis-atracurium
______doxacurium

The first nondepolarizing NMBAs (curare, gallamine, metocurine), which were

introduced into clinical practice in the 1940s, are rarely if ever used in today's clinical practice. The past 20 years have seen a rapid growth in the development and introduction of nondepolarizing NMBAs for clinical use. As these agents have more favorable profiles (onset times, recovery times, metabolic fate), they have displaced the original group introduced in the 1940s.

Pancuronium

Pancuronium is an aminosteroid compound, generally available in a solution containing 1 mg/mL of pancuronium (depending on the manufacturer, other concentrations may be available). The common clinical dose of 0.1 to 0.15 mg/kg provides adequate conditions for endotracheal intubation in 90 to 120 seconds. Although the higher end of the dosing range may speed the onset time for acceptable conditions for endotracheal intubation, the clinical duration is prolonged from 40 to 60 minutes to 70 to 80 minutes. Given its duration of action, pancuronium is considered a long-acting NMBA (Table 133.5). The ED_{95} in children is 52 μg/kg during halothane anesthesia and 81 to 93 μg/kg during an opioid-based anesthetic. The latter is more applicable to the PICU setting.[37] The ED_{95} in children is slightly higher than that of adolescents.[38] Following a dose of 70 μg/kg, the onset of neuromuscular blockade occurs more quickly in children than in adults with 90% twitch ablation occurring at an average of 2.4 minutes in children and 4.3 minutes in adults.[39] The time to return of the twitch height to 10% of baseline was 25 minutes in children and 46 minutes in adults.

TABLE 133.5
Duration of Action of Neuromuscular Blocking Agents

Short-acting (10 min):
______succinylcholine
______mivacurium
______rapacuronium
Intermediate-acting (20-40 min):
______atracurium
______vecuronium
______cis-atracurium
______rocuronium
Long-acting (60-90 min):
______pancuronium
______pipecuronium
______doxacurium

Vagal blockade and release of norepinephrine from adrenergic nerve endings result in an increase in heart rate and blood pressure. Intraoperatively, this effect was used to balance the negative chronotropic effects of the volatile anesthetic agent, halothane. There may be a mild proarrhythmogenic effect for atrial

tachyarrhythmias in patients with comorbid diseases or when administered with other agents that increase heart rate. Elimination is primarily renal (80%), resulting in a significantly prolonged effect with renal insufficiency or failure. Hepatic metabolism is primarily hydroxylation with production of an active 3-OH metabolite, which retains approximately 50% of the neuromuscular blocking effects of the parent compound. The 3-OH metabolite is also dependent on renal excretion, thereby further prolonging the effect in the setting of renal insufficiency or failure.

Given its longer half-life, pancuronium is generally used by intermittent dosing to provide ongoing neuromuscular blockade in the PICU setting. One prospective study evaluated dosing requirements in the PICU population with pancuronium administration by a continuous infusion.[40] Pancuronium was administered as an initial bolus dose of 0.1 mg/kg followed by an infusion starting at 0.05 mg/kg/hr. The infusion was titrated up and down to maintain one to two twitches of the TOF (see later). Pancuronium infusion requirements varied from 0.3 to 0.22 mg/kg/hr with an average infusion rate of 0.07 ± 0.03 mg/kg/hr for the 1798 hours of the infusion. Approximately 70% of the time, the infusion requirements varied from 0.05 to 0.08 mg/kg/hr. Increased infusion requirements were noted in patients receiving anticonvulsant agents (0.14 ± 0.06 vs. 0.056 ± 0.03 mg/kg/hr) and in patients who received pancuronium for more than 5 days (day 1 requirements of 0.059 mg/kg/hr vs. 0.083 mg/kg/hr on day 5). On discontinuation of the infusion, time to spontaneous recovery of neuromuscular function (return of the TOF to baseline and sustained tetanus to 50 Hz) varied from 35 to 75 minutes. The authors concluded that pancuronium could be effectively administered by continuous infusion to provide neuromuscular blockade in the PICU setting, being a cost-effective alternative to other available agents in many clinical scenarios. Despite its efficacy in many clinical situations, the use of pancuronium has decreased markedly over the past 20 years, since the introduction of intermediate-acting agents with limited concerns of prolonged blocking following intraoperative use. With the availability of generic forms of vecuronium, the cost advantages of pancuronium have decreased, thereby limiting its use.

Vecuronium

Like pancuronium, vecuronium is an aminosteroid compound. It was released for clinical use in the 1980s. Despite minor differences in pharmacologic structure from pancuronium, its plasma clearance is two to three times as rapid. Vecuronium is available as a powder (10 mg), which in common clinical practice is diluted to a concentration of 1 mg/mL. Its initial introduction and acceptance into anesthesia practice were facilitated by its lack of clinically significant hemodynamic effects as it does not cause tachycardia or hypotension. In the usual clinically used doses of 0.1 to 0.15 mg/kg, acceptable conditions for endotracheal intubation are present in 80 to 90 seconds with a clinical duration of action of 30 to 40 minutes, making it an intermediate-acting agent.[41] To speed the onset and allow for endotracheal intubation in 60 to 75 seconds, the dose can be increased to 0.3 mg/kg. However, higher doses resulted in a prolonged duration of neuromuscular blockade of 60 to 90 minutes. Even with higher doses, vecuronium is devoid of cardiovascular effects. Metabolism is primarily hepatic (70%-80%); however, hepatic metabolism results in the production of pharmacologically active metabolites, which are water soluble and therefore dependent on renal excretion. These metabolites possess roughly half of

the neuromuscular blocking effects of the parent compound. This combined with the 20% to 30% renal excretion of the parent compound results in a prolonged clinical duration in patients with renal insufficiency. Given its 70% to 80% dependency on hepatic metabolism, the duration of action is also prolonged with hepatic insufficiency and in neonates due to immaturity of the hepatic microsomal enzymes. Vecuronium in doses of 0.1 mg/kg and 0.15 mg/kg maintained neuromuscular blockade at 90% or more of baseline for 59 and 110 minutes in neonates and infants, 18 and 38 minutes in children, and 37 and 68 minutes, respectively, in adolescents.[42] The opposite effect occurs with the chronic administration of anticonvulsant agents with resistance to the neuromuscular blocking effects and increased dose requirements in patients receiving phenytoin.[43] A similar effect has been reported with other anticonvulsant agents and other NMBAs of the aminosteroid group. Given its lack of hemodynamic effects and current availability in generic form, thereby providing a cost-effective agent for neuromuscular blockade, vecuronium remains a commonly used agent by bolus dosing and continuous infusion for neuromuscular blockade in the PICU setting. As with many generic medications, intermittent medication shortages have included vecuronium over the past 5 years.

Rocuronium

Rocuronium is an aminosteroid NMBA that was released for clinical use in the early to mid 1990s. It is commercially available in a solution containing 10 mg/mL in either 5- or 10-mL vials. Following the routine dose for endotracheal intubation of 0.6 mg/kg, the duration of action is 20 to 40 minutes, making it an intermediate-acting agent; however, larger doses (1–1.2 mg/kg) are frequently used during rapid sequence or urgent/emergent endotracheal intubation as the onset time with these doses has been shown to approximately parallel those of succinylcholine (see later). As with other agents, the duration of action increases when larger doses are administered so that 60 to 90 minutes of neuromuscular blockade generally occur following a dose of 1.0 mg/kg. Of note, given its dependence on hepatic metabolism, a prolonged effect may be seen in neonates and infants. A mild vagolytic effect, less in intensity than that seen with pancuronium, may increase heart rate in the range of 10 to 20 beats per minute and mean arterial pressure following bolus dosing.

Rocuronium undergoes primarily hepatic metabolism without the production of active metabolites, which have a clinical effect following a single bolus dose. Its clinical duration is prolonged, and its clearance is decreased in patients with hepatic insufficiency or failure. Despite its primary dependence on hepatic elimination, there are mixed results in both adults and children regarding the duration of its effects in patients with renal insufficiency or failure. When comparing adults with and without renal failure, Robertson et al. reported that there was prolongation of the clinical duration (time to recovery of the first twitch of the TOF to 25% of baseline) from 32 to 49 minutes following a dose of 0.6 mg/kg in patients with renal failure.[44] The same investigators reported no difference in the pharmacodynamics in adults with and without renal failure with the use of a smaller dose (0.3 mg/kg).[45] With the smaller dose of 0.3 mg/kg, the onset time was 4 minutes and neuromuscular blockade was reversible at 20 minutes. When comparing adults with renal failure and those with normal renal function, Cooper et al.[46] reported that following rocuronium (0.6 mg/kg), onset time (65 ± 16 vs. 61 ± 25 seconds), clinical duration (55 ± 26.9 vs. 42 ± 9.3 minutes), and spontaneous recovery (time for return of the final

twitch of the TOF to 70% of baseline) were all prolonged (99 ± 41 vs. 73 ± 24 minutes). Following an initial dose of 0.3 mg/kg, pediatric patients with renal failure had a longer onset time (139 ± 71 vs. 87 ± 43 seconds); however, there was no difference in the clinical duration.[47] More specific pharmacokinetic data and an explanation for the apparent prolonged elimination half-life of rocuronium in renal failure patients are provided by Szenohradszky et al.[48] in their evaluation of rocuronium in a cohort of 10 adult patients undergoing renal transplantation. Following a dose of 0.6 mg/kg, although the total plasma clearance and volume of the central compartment did not differ between renal failure and control patients, the volume of distribution at steady state was larger in patients with renal failure and this resulted in a longer elimination half-life with renal failure (97.2 ± 17.3 vs. 70.9 ± 4.7 minutes). A summary of these studies demonstrates a slightly prolonged onset time with rocuronium and a prolonged elimination half-life (and therefore a prolonged clinical effect) in the presence of renal failure. Current data suggest that these findings result from alterations in the volume of distribution rather than primary alterations in clearance due to renal effects. The prolonged duration of action may be clinically significant with doses 0.6 mg/kg or greater and can be minimized with doses of 0.3 mg/kg. However, with the smaller doses, onset times for successful endotracheal intubation will be prolonged to 2 to 3 minutes.

Given its dependence on hepatic metabolism, alterations in clearance are likely in not only patients with primary hepatic diseases but also neonates and infants due to the immaturity of the hepatic microsomal enzymes. When comparing infants (0.1-0.8 years) and children (2.3-8 years), plasma clearance is decreased (4.2 ± 0.7 vs. 6.7 ± 1.1 mL/kg/min), the volume of distribution is increased (231 ± 32 vs. 165 ± 44 mL/kg), and the mean residence time is increased (56 ± 10 vs. 26 ± 9 minutes).[49] Also of note, the plasma concentration required to exert a 50% neuromuscular blocking effect is decreased in neonates and infants compared with older children (1.2 ± 0.4 vs. 1.7 ± 0.4 mg/mL). The latter effect, which indicates that the neuromuscular junction of neonates and infants is more sensitive to the effects of NMBAs, is not specific for rocuronium and is seen with all NMBAs. Similar results were reported by Rapp et al.[50] as they reported progressive increases in the clinical duration with a decrease from 5 to 12 months to 2 to 4 months to 0 to 1 month of age. The effect was further magnified when increasing the dose from 0.45 to 0.6 mg/kg. The authors also reported excellent or good conditions for endotracheal intubation in all infants with doses of 0.45 mg/kg and ablation of the twitch response at 15 to 30 seconds in neonates, thereby demonstrating a rapid onset even with the use of lower doses (0.45 mg/kg). As with other medications that undergo primary hepatic metabolism, the clinical effects of rocuronium are prolonged in neonates and infants. Metabolism and clinical effects approach those of the adult population by 6 to 12 months of age. In the neonate or younger infant, acceptable conditions for endotracheal intubation can be achieved at 45 to 60 seconds with doses of 0.3 to 0.45 mg/kg.

The acceptance of rocuronium into the clinical arena has been expedited by its reported clinical advantage over other nondepolarizing NMBAs, a rapid onset. Clinical studies have demonstrated acceptable conditions for endotracheal intubation in the majority of older children and adolescents within 60 seconds following a dose of 1.0 mg/kg. Of the currently available nondepolarizing NMBAs, only rocuronium has an onset of action comparable with that of succinylcholine. The remainder of the NMBAs require 90 to 120 seconds to provide conditions acceptable

for endotracheal intubation even when larger doses are used. In both the pediatric and adult populations, various studies have demonstrated that rocuronium in a dose of 1 mg/kg provides acceptable conditions for endotracheal intubation within 60 seconds in the majority of patients.[51-53] Mazurek et al.[52] prospectively compared the onset times of rocuronium (1.2 mg/kg) and succinylcholine (1.5 mg/kg) in a cohort of 26 children. Anesthesia was induced with thiopental (5 mg/kg). Endotracheal intubation attempts were started 30 seconds after the administration of the agent. Time to endotracheal intubation was comparable between the two groups (41.8 ± 2.9 seconds, range: 36-45 seconds with succinylcholine and 40.2 ± 4.0 seconds, range: 33-48 seconds with rocuronium). However, the conditions for endotracheal intubation were slightly less favorable with rocuronium as 7 were excellent, 5 good, and 1 fair versus 10 excellent, 2 good, and 1 fair with succinylcholine. Schreibner et al.[53] compared conditions for endotracheal intubation provided by three of the commonly used NMBAs (rocuronium 0.6 mg/kg, vecuronium 0.1 mg/kg, and atracurium 0.5 mg/kg). Endotracheal intubation was attempted every 30 seconds. Conditions for all of the endotracheal intubations were graded as excellent or good, 60 seconds after rocuronium, 120 seconds after vecuronium, and 180 seconds after atracurium. Although a larger dose of rocuronium speeds the onset time to acceptable conditions for endotracheal intubation, there is also a prolonged duration of action (60-80 minutes) unlike that of succinylcholine (5-10 minutes). The longer duration of action may be problematic should difficulties arise with the performance of endotracheal intubation resulting in a “cannot intubate–cannot ventilate” scenario. Additionally, in patients with traumatic brain injury or other conditions resulting in alteration of mental status, the neurologic examination will be lost for 60 to 80 minutes following rocuronium in doses of 1 mg/kg. Despite these issues, because of its rapid onset, rocuronium remains the drug of choice for rapid sequence or urgent/emergent endotracheal intubation when there are concerns regarding the use of succinylcholine (see earlier).

Various investigators have evaluated potential techniques to increase the onset time of rocuronium without the need to increase the dose. Although there was no difference noted in the time to 50% blockade (42 ± 14 vs. 45 ± 10 seconds) or onset time when comparing rocuronium 0.6 mg/kg administered with either ketamine 1.5 mg/kg or thiopental 4 mg/kg in parturients, endotracheal intubation at 50% blockade was easily performed in all patients in the ketamine group while it was difficult in 75% of patients who received thiopental.[54] A significant decrease in the onset time of rocuronium (0.6 mg/kg) was also demonstrated in patients who received ephedrine (70 μg/kg), 30 seconds before the start of rapid-sequence endotracheal intubation compared with patients receiving placebo (72 ± 19 vs. 98 ± 31 seconds).[55] As ephedrine increases cardiac output through the release of endogenous catecholamines, drug delivery to the skeletal muscle is increased, thereby accelerating the onset time.

As with other NMBAs such as vecuronium, the principle of priming has been used to accelerate the onset time of rocuronium.[56] Eighty-four children undergoing endotracheal intubation were randomized into one of four groups: (1) saline-rocuronium 0.45 mg/kg, (2) rocuronium 0.045 mg/kg–rocuronium 0.405 mg/kg, (2) saline, (3) rocuronium 0.6 mg/kg, or (4) rocuronium 0.06–rocuronium 0.054 mg/kg. The median onset times and 95% confidence in the 4 groups were 122.5 (8–186), 92.5 (68–116), 85 (60–142), and 55 (48–72) seconds, respectively, thereby demonstrating a

clinical advantage of priming regardless of whether the total dose was 0.45 or 0.6 mg/kg. As noted previously, there may be issues with priming including the potential to induce upper airway or respiratory muscle weakness with the potential for aspiration, airway obstruction, or hypoventilation, especially in critically ill patients even with the small priming dose. Additionally, the majority of studies that have used priming have waited at least 60 seconds from the administration of the priming dose until the administration of the remainder of the dose, thereby prolonging the process of medication administration for endotracheal intubation.

Given its rapid onset and lack of adverse effects, most notably rhabdomyolysis and hyperkalemia with underlying neuromuscular disorders, the use of rocuronium via the IM route instead of succinylcholine in the treatment of emergencies, such as laryngospasm during anesthetic induction when IV access is lacking, would be clinically applicable. However, when evaluating onset and recovery times following IM rocuronium, adequate or good to excellent intubating conditions took an average of 2.5 minutes in infants following a dose of 1 mg/kg and 3 minutes in children following a dose of 1.8 mg/kg.[57] The clinical duration was 57 ± 13 minutes in infants and 70 ± 23 minutes in children. The authors also demonstrated a more rapid and predictable onset with IM administration into the deltoid as compared with the quadriceps muscle, an effect similar to that noted with succinylcholine (see earlier). Given these onset times, the authors concluded that IM rocuronium was not an alternative to IM succinylcholine for the emergent treatment of laryngospasm.

An additional issue with rocuronium in clinical practice includes pain on injection through a peripheral IV cannula.[58] When rocuronium is administered immediately after the induction agent for endotracheal intubation, limb withdrawal and grimacing may be seen. The incidence of pain has been reported to be as high as 50% to 80% with a higher incidence in women than men. As with propofol, various techniques have been suggested to prevent or lessen this problem including diluting the rocuronium solution to 0.5 mg/mL instead of the commercially available 10 mg/mL or the preadministration or coadministration of various pharmacologic agents including lidocaine, ketamine, dexmedetomidine, thiopental, magnesium, alfentanil, and ondansetron.[58,59] All of these have met with varying degrees of success. When rocuronium is coadministered with thiopental into the same IV site, a precipitate may form and occlude the IV cannula or tubing. This problem can be prevented by thoroughly flushing the IV site between the thiopental and rocuronium. As with the other aminosteroid NMBAs, chronic anticonvulsant therapy causes resistance to the neuromuscular blocking effects of rocuronium.[60] This effect is mediated by not only stimulation of the hepatic microsomal enzymes responsible for metabolism of these medications but also the upregulation of acetylcholine receptors given their low-grade antagonism of these receptors at the neuromuscular junction.

Although used most commonly by bolus injection for rapid-sequence endotracheal intubation, there are reports of the use of rocuronium infusions in the PICU setting.[61] Given the current problem with the intermittent shortages of various medications including vecuronium, at times rocuronium may be the only intermediate age in the aminosteroid class that is available for clinical use. In a cohort of 20 PICU patients, rocuronium was administered by continuous infusion to maintain one to two twitches of the TOF. The duration of the rocuronium infusion varied from 26 to 172 hours with a total of 1492 hours of administration. Following

the initial bolus dose of 0.6 mg/kg, there was a mild increase in heart rate and blood pressure. The infusion requirements on day 1 varied from 0.3 to 0.8 mg/kg/hr (0.76 ± 0.3 mg/kg/hr). When evaluating all patient days, the infusion requirements varied from 0.3 to 2.2 mg/kg/hr (0.95 ± 0.4 mg/kg/hr). The infusion requirements were 0.5 to 0.8 mg/kg/hr in 45 of the 64 patient days (70%) and 0.3 to 1.0 mg/kg/hr in 58 of the 64 patient days (90%). As with other agents, there was an increase in infusion requirements over time. In 14 patients who received rocuronium for 3 days or more, infusion requirements increased from 0.65 mg/kg/hr on day 1 to 0.84 mg/kg/hr on day 3. In five patients who received rocuronium for 5 days, the infusion requirements increased from 0.67 mg/kg/hr on day 1 to 1.2 mg/kg/hr on day 5. When the infusion was discontinued, spontaneous return of neuromuscular function occurred in 24 to 44 minutes (31 ± 12 minutes). No adverse effects related to the use of rocuronium were noted.

Pipecuronium

Pipecuronium is structurally related to the other aminosteroids including pancuronium and vecuronium. Like vecuronium, it is devoid of cardiovascular effects. Following the clinically recommended dose for endotracheal intubation of 0.07 mg/kg, onset times vary from 2 to 3 minutes with a longer duration of action (70 to 80 minutes) than pancuronium. Pipecuronium is eliminated primarily by the kidneys (80%) with the remainder of the elimination dependent on hepatic metabolism. There is limited clinical information concerning the use of pipecuronium in the pediatric population, being used primarily for intraoperative neuromuscular for prolonged surgical procedures.[62-64]

Rapacuronium

In an effort to meet the need for a nondepolarizing NMBA whose onset and offset parallel that of succinylcholine, rapacuronium was introduced into clinical practice in the United States in 1998. The initial clinical experience demonstrated a rapid onset, paralleling that of succinylcholine or larger doses of rocuronium, with a recovery time of less than 10 minutes, thereby offering a significant clinical advantage over rocuronium. Hemodynamic effects included a mild tachycardia like other aminosteroid NMBAs related to a vagolytic effect. Metabolism was hepatic with the presence of active metabolites that were dependent on renal excretion, although their presence did not appear to result in a clinically significant duration of action even in the presence of renal failure or insufficiency.

Unfortunately, with increased clinical use came the recognition that profound and even potentially fatal bronchospasm were associated with its administration. Although these problems were initially postulated to result from an inadequate depth of sedation/anesthesia during airway instrumentation, subsequent studies suggested a direct effect on the cholinergic receptors of the airway. In a retrospective review of their clinical database, Rajchert et al. reported that bronchospasm occurred in 12 of 287 (4.2%) of patients receiving rapacuronium.[65] Five of the episodes with rapacuronium resulted in an inability to move the chest with no exhaled end-tidal CO_2 following endotracheal intubation. The risk of bronchospasm was 10.1 times greater with rapacuronium compared with other NMBAs. Additional clinical data demonstrating the potential for alterations in respiratory compliance and resistance

were reported in a prospective trial in 20 adults randomized to receive either cis-atracurium or rapacuronium.[66] Rapacuronium was administered following anesthetic induction and endotracheal intubation during general anesthesia using continuous infusions of propofol and remifentanil. No changes in compliance or resistance of the respiratory system were noted following cis-atracurium. Following the administration of rapacuronium administration, peak inflating pressure increased from 22 ± 6 to 28 ± 9 cm H_2O, compliance decreased from 108 ± 43 to 77 ± 41 mL/cm H_2O, peak inspiratory flow rate decreased from 0.43 ± 0.11 to 0.39 ± 0.09 L/sec, peak expiratory flow rate decreased from 0.67 ± 0.10 to 0.59 ± 0.09 L/sec, and tidal volume decreased from 744 ± 152 to 647 ± 135 mL. Mechanisms for rapacuronium's effects on airways have focused on alterations in cholinergic function with antagonism of the M_2 muscarinic receptor, augmentation of acetylcholine effects at the M_3 muscarinic receptor, and potentiation of vagal nerve and acetylcholine-induced bronchoconstriction.[67,68] The M_2 muscarinic mechanism may be of particular interest as various NMBAs have been shown to have differing degrees of activity at this receptor. These effects have been reported with pipecuronium and even with rocurnium.[69,70]

During normal function at the neuromuscular junction of smooth muscle including the airway, some of the acetylcholine that is released diffuses back to the prejunctional (M_2) receptor and shuts off ongoing acetylcholine release. Thus the M_2 receptor is a negative feedback receptor that regulates acetylcholine release. With blockade of the M_2 receptor, there may be exaggerated release of acetylcholine and hence exaggerated muscle contraction or bronchospasm. Although rapacuronium was removed from the market in 2001, there may be other NMBAs in the clinical development process and their potential activity at the M_2 receptor warrants attention and investigation.

Mivacurium

Mivacurium is a benzylisoquinolinium NMBA, which is the shortest acting of the nondepolarizing NMBAs, undergoing non–organ-dependent elimination (see later). It was introduced into clinical practice in the 1980s and then, given its low market share, was eliminated from the US market for approximately 5 to 10 years. However, given ongoing interest in its potential intraoperative applications, the medication is likely to be rereleased into the US market in the next year or two. Mivacurium was previously available in a premixed solution in a concentration of 2 mg/mL in 5- or 10-mL vials. Following a dose of 0.2 mg/kg, onset times vary from 2 to 3 minutes with a duration of action of approximately 10 minutes. In a cohort of 62 children anesthetized with nitrous oxide and fentanyl, mivacurium infusion rates to maintain neuromuscular blockade were 375 ± 19 μg/m^2/min with a spontaneous recovery time (T_4/T_1 ≥0.75) of 9.8 ± 0.4 minutes.[71] There was no evidence of accumulation during prolonged infusions.

Mivacurium is metabolized by nonspecific plasma cholinesterases. Prolonged blockade can occur in the same clinical situations as described with succinylcholine (see earlier) including congenital and acquired deficiencies of the enzyme system, butyrylcholinesterase, also known as pseudocholinesterase or plasma cholinesterase.[72,73] The metabolites of mivacurium, which are renally excreted, have

limited neuromuscular blocking properties. As with the other benzylisoquinoliniums, mivacurium can produce histamine release. In children, the histamine release may be associated with flushing and erythema of the skin; however, the hemodynamic effects are generally of limited clinical significance.[74]

The potential application for mivacurium in clinical practice has been when neuromuscular blockade is required for brief procedures (<10 minutes) in either the operating room or PICU. Mivacurium can be a useful agent to provide a brief duration of neuromuscular blockade for direct laryngoscopy in the PICU to follow the progression of airway problems and then allow for the prompt spontaneous return of neuromuscular function. In the intraoperative setting, the rapid and spontaneous recovery of neuromuscular function eliminates the need for the use of reversal agents such as neostigmine (see later) that may increase the incidence of postoperative nausea and vomiting.

Another potential use for mivacurium has been in combination with other nondepolarizing NMBA to provide a rapid onset of neuromuscular blockade and yet avoid the prolonged duration seen when large doses of vecuronium (0.3 mg/kg) or rocuronium (1–1.2 mg/kg) are administered.[75,76] The onset time to 90% neuromuscular blockade was 39 ± 2.3 seconds with 1 mg/kg succinylcholine and 48 ± 3.5 seconds with vecuronium 0.16 mg/kg and mivacurium 0.2 mg/kg.[75] Conditions for endotracheal intubation were graded as excellent in 10 of 10 patients in both groups. Despite the rapid onset, recovery times were prolonged with the combination of vecuronium and mivacurium. Similar results were reported with a combination of mivacurium 0.2 mg/kg and rocuronium 0.6 mg/kg.[76] Although the onset times paralleled that of succinylcholine, the recovery times (49.0 ± 9.6 minutes) were prolonged.

Mivacurium may also be potentially advantageous in patients with underlying neuromuscular disorders (ie, muscular dystrophy). In such patients, prolonged neuromuscular blockade may occur even following a single dose of intermediate-acting agents such as vecuronium, atracurium, or cis-atracurium. Therefore the use of an agent with the shortest clinical duration may be beneficial.[77-79] When compared with healthy control subjects, although there was no difference noted in the onset times, patients with Duchenne muscular dystrophy demonstrated only a modest prolongation of the clinical effect of mivacurium.[77] The median times for recovery of the first twitch of the TOF to 10%, 25%, and 90% of baseline in controls and patients with muscular dystrophy were 8.4 versus 12.0 minutes, 10.5 and 14.1 minutes, and 15.9 and 26.9 minutes. Similar results were demonstrated in another cohort of 7 children with Duchenne muscular dystrophy.[78] Following a dose of 0.2 mg/kg, time to recovery of the first twitch varied from 12 to 18 minutes. They also noted significant interpatient variability with infusion requirements varying from 3–20 µg/kg/min. Five of the seven patients required less than or equal to 10 µg/kg/min, further demonstrating increased sensitivity to this agent in patients with muscular dystrophy. Of note, there was no correlation with infusion requirements and the patient's preoperative motor function.

Atracurium

Atracurium is a nondepolarizing NMBA of the benzylisoquinolinium class, which was released for clinical use in the 1980s. It is supplied in a 10-mg/mL solution. Following a dose of 0.6 mg/kg, acceptable conditions for endotracheal intubation are

achieved in 2 to 3 minutes with complete twitch suppression for 15 to 20 minutes followed by another 10 to 15 minutes with a variable degree of blockade (twitch height 5%-25%). Spontaneous recovery ($T_4/T_1 \geq 0.7$) generally occurs in 40 to 60 minutes. As with all of the NMBAs, the use of a smaller dose (0.3–0.4 mg/kg) is feasible but will prolong the time to the onset of acceptable conditions for endotracheal intubation, as well as shortening the recovery time. Atracurium's recovery profile makes it an intermediate-acting agent. As with other NMBAs of the benzylisoquinolinium class, atracurium can lead to histamine release, thereby limiting dose escalations to speed the onset of neuromuscular blockade. Although facial cutaneous flushing and erythema may occur as with mivacurium, effects on heart rate and blood pressure are generally minimal following doses up to 0.6 mg/kg.[80] With larger doses, hypotension may occur. In the pediatric-aged patient, histamine release is less frequent and less profound than in adults. Even when histamine release occurred, no hemodynamic changes were noted.[81] Following its introduction into clinical practice, ongoing safety surveillance demonstrated no difference in the adverse effect profile of atracurium related to histamine release when compared with other NMBAs.[82] Extremely rare, anecdotal case reports exist regarding anaphylactoid reactions with severe bronchospasm temporally related to its administration; however, a true causal relationship cannot be proven as the patients also received thiopental during anesthetic induction.[83]

Atracurium undergoes spontaneous degradation via a process known as Hofmann elimination and ester hydrolysis. Therefore its duration of action is unchanged in the presence of renal or hepatic insufficiency or failure. Because of these properties, it rapidly gained favor for providing neuromuscular blockade in ICU patients, generally by continuous infusion (see later). Although the metabolites of atracurium do not possess significant neuromuscular blocking properties, one of the metabolic byproducts of Hofmann degradation, laudanosine, has been shown to be epileptogenic in animals. The actual concentrations required to cause seizures in humans is unknown, and no formal study has ever documented clinical effects from a high laudanosine level. Laudanosine is renally excreted, and its accumulation in patients with renal insufficiency is at least a theoretical concern.

Infusion requirements to maintain clinical neuromuscular blockade, defined as a single twitch height of 1% to 10% of baseline, averaged 9 μg/kg/min during a nitrous oxide-opioid based anesthetic.[84] Recovery remains predictable and stable regardless of the duration of the infusion. Within 30 minutes of discontinuation of the infusion, twitch height had spontaneously recovered to $T_4/T_1 \geq 0.7$.[85] Reversal of neuromuscular blockade with neostigmine (see later) is generally feasible within 10 to 15 minutes of discontinuing an infusion or following the administration of a single dose of 0.6 mg/kg. When compared with a longer-acting agent such as pancuronium, spontaneous recovery following a continuous infusion occurred at an average time of 15 minutes (range 6-34 minutes) with atracurium compared with 25 minutes (10.5-37 minutes) with pancuronium.[86] Given its intermediate duration of action and stable recovery profile, atracurium has been used safely and effectively in patients with neuromuscular disorders including myasthenia gravis, myotonic dystrophy, and muscular dystrophy.[87,88] However, prolonged neuromuscular blockade with a recovery time of 3 to 4 hours has also been reported following a single dose of 0.6 mg/kg.

Given its predictable recovery characteristics in most patient populations, its

limited hemodynamic effects, and its lack of dependence on end-organ function for elimination, atracurium remains a popular agent for neuromuscular blockade in the PICU setting. In a cohort of 20 infants and children requiring neuromuscular blockade for 10 to 163 hours during mechanical ventilation, the mean effective dose of atracurium was 1.4 mg/kg/hr (range: 0.44–2.4 mg/kg/hr).[89] When no TOF could be elicited, the time required for the first twitch to become evident with discontinuation of the infusion was only 13.8 minutes (range: 1-38 minutes). The authors reported that there was no correlation between the recovery time and dose being administered; however, they did note a faster recovery time when the infusion had been administered for more than 48 hours. Given its non–organ-dependent elimination, atracurium has also been used in pediatric patients following orthotopic liver transplantation.[90] Recovery time ($T_4/T_1 \geq 0.7$) when the infusion was discontinued averaged 23.6 minutes (range: 12-27 minutes) and was not prolonged compared with the general pediatric population.

As with rocuronium, administration with thiopental and other barbiturates may result in precipitation and occlusion of the IV cannula, necessitating flushing the line with normal saline between these 2 agents. As Hofmann elimination is a temperature-dependent process, elimination will be prolonged during induced or inadvertent hypothermia.[91] During induced hypothermia (32°C) in a cohort of children, atracurium infusion requirements were 784 μg/kg/hour or 56% of that in normothermic children (1411 μg/kg/hour). Recovery times were also prolonged to two to three times those in normothermic patients. A similar effect has been reported with the cis-atracurium during hypothermia (see later).

Cis-atracurium

Cis-atracurium is one of the stereoisomers contained in solutions of atracurium. It is six to eight times as potent as atracurium but devoid of clinically significant histamine release and hemodynamic effects.[92] Cis-atracurium is available as a 2-mg/mL solution. Like atracurium, cis-atracurium is an intermediate-acting neuromuscular blocking agent with a duration of action of 20 to 30 minutes following a bolus dose of 0.2 mg/kg. Acceptable conditions for endotracheal intubation are provided in approximately 2 minutes. In a cohort of 80 adult patients, cis-atracurium in doses of 0.1, 0.15, and 0.2 mg/kg provided acceptable conditions for endotracheal intubation in 4.6, 3.4, and 2.8 minutes with a clinically effective duration of 45, 55, and 61 minutes.[93] In a cohort of 27 infants (1-23 months of age) and 24 children (2-12.5 years of age), the onset time to achieve maximal blockade following a dose of 0.15 mg/kg was more rapid in infants (2.0 ± 0.8 vs. 3.0 ± 1.2 minutes, $P = 0.0011$).[92] The clinical duration (recovery to 25% of baseline) was longer in infants (43.3 ± 6.2 vs. 36.0 ± 5.4 minutes, $P < 0.0001$). Once neuromuscular started to recovery, the rate of recovery was similar between the two groups. However, de Ruiter et al.[94] reported no difference in the ED_{50}, ED_{95}, or infusion rate required to maintain 90% to 99% block when comparing 32 infants (0.3-1 year of age) and 32 children (3.1-9.6 years of age). The ED_{50} in the two groups was 29 ± 3 versus 29 ± 2 μg/kg, the ED_{95} was 43 ± 9 versus 47 ± 7 μg/kg, and the infusion rate required to maintain 90% to 99% blockade in the two groups was 1.9 ± 4 versus 2.0 ± 0.5 μg/kg/min.

A prospective study evaluated cis-atracurium dosing requirements in 15 PICU

patients ranging in age from 10 months to 11 years and in weight from 4 to 28 kgs.[95] The cis-atracurium infusion was adjusted to maintain one twitch of the TOF. Infusion requirements varied from 2.1 to 3.8 μg/kg/min (average of 3.1 ± 0.6 μg/kg/min) on day 1, from 2.9 to 8.1 μg/kg/min (average of 4.5 ± 1.6 μg/kg/min, P <0.01 compared with day 1) on day 3, and from 1.4 to 22.7 μg/kg/min during all patient days. The highest infusion requirements were noted following the administration of the drug for prolonged periods of time (150 and 224 hours). When the infusion was discontinued, spontaneous return of neuromuscular function was noted in 14 to 33 minutes. Effective neuromuscular blockade was provided and no adverse effects related to cis-atracurium were noted. In particular, no hemodynamic changes were noted with bolus dosing. Odetola et al.[96] evaluated the dosing requirements of cis-atracurium in a cohort of 11 PICU patients, ranging in age from 0 to 2 years. The duration of the infusions varied from 14 to 122 hours (64.5 ± 36 hours). The infusion requirements to maintain 90% to 95% neuromuscular blockade were 5.36 ± 3.0 μg/kg/min. Laudanosine concentrations during the infusion were 163.3 ± 116 ng/mL. As in the previous study, there was an increase in dose requirements over time and no hemodynamic effects were noted with cis-atracurium.

Reich et al.[97] compared vecuronium and cis-atracurium, administered by continuous infusion, to provide neuromuscular blockade following surgery for congenital heart disease in a cohort of 19 patients younger than 2 years of age. The NMBA was administered to maintain one twitch of the TOF with median infusion times of 64.5 hours for cis-atracurium and 46 hours for vecuronium. Median recovery time, defined as a normal TOF without fade, was shorter with cis-atracurium than with vecuronium (30 minutes vs. 180 minutes, P <0.05). Recovery time was more than 4 hours in 3 of 9 patients who received vecuronium. Two of these patients had high vecuronium plasma concentrations while the other had an elevated 3-OH vecuronium level. There was no difference in time to tracheal extubation, ICU stay, or hospital stay.

As with other NMBAs, resistance to the effects of cis-atracurium may be seen in patients treated with anticonvulsant agents.[98] Time to recovery of T_1 to 25% of baseline was 69 ± 13 minutes in patients not receiving anticonvulsant medications, 64 ± 19 minutes in those receiving acute therapy with anticonvulsants, and 59 ± 19 minutes in those receiving chronic anticonvulsant therapy. As with atracurium, altered clearance and decreased infusion requirements are noted during decreases in body temperature.[99] During induced hypothermia (34°C) to control increased ICP, cis-atracurium infusion requirements decreased to 1.7 μg/kg/min and increased to 3.4 μg/kg/min with return to normothermia.

Doxacurium

Doxacurium is the benzylisoquinolinium derivative with the longest duration of clinical activity. Although still available for clinical use, its clinical applications are limited with limited data regarding its use in the PICU setting. It is the most potent of the clinically available NMBAs with approximately twice the potency of pancuronium or pipecuronium. Following a dose of 0.05 mg/kg, its duration of action is 80 to 90 minutes. The ED_{95} in children is 30 μg/kg, approximately 1.5 times that reported for the adult population.[100] Elimination is primarily renal with a small

percentage dependent on hepatic excretion. The duration of action is prolonged in patients with either hepatic or renal insufficiency. Despite it being a benzylisoquinolinium derivative, it is primarily devoid of histamine-releasing properties and cardiovascular or hemodynamic effects.

Reversal of Neuromuscular Blockade

Although neuromuscular blockade is necessary for many surgical procedures or used for various indications in the PICU setting, even a small residual amount of blockade may compromise ventilation or upper airway patency in the critically ill patient or during the immediate postoperative period. In the operating room setting, residual neuromuscular blockade is frequently reversed at the completion of the procedure to ensure adequate strength to maintain airway patency and ventilatory function following extubation of the trachea.[101] In the PICU setting, reversal of neuromuscular blockade is less common. In most clinical scenarios, when there is no longer a need for neuromuscular blockade, the agent is discontinued and spontaneous recovery is allowed. The latter is generally appropriate in the PICU setting, as ongoing tracheal intubation and mechanical ventilation will likely be provided for some period of time following the discontinuation of the NMBA.

Reversal of neuromuscular blockade is possible only with nondepolarizing NMBAs. Additionally, some degree of residual neuromuscular function is necessary to allow for effective reversal of neuromuscular blockade. In general clinical practice, this means that there should be one to two twitches in the TOF or that the T_1 has recovered to 25% of its baseline height. Reversal of neuromuscular blockade with a drug that inhibits acetylcholinesterase is not feasible immediately after the administration of an NMBA. Depending on the dose administered, some time, generally 15 to 30 minutes with intermediate-acting agents, is necessary (see later for a discussion of reversal of neuromuscular blockade with sugammadex).

The medications used to reverse neuromuscular blockade inhibit the enzyme acetylcholinesterase. This, in turn, provides more acetylcholine to compete with the NMBA at the nicotinic receptor of the neuromuscular junction. The commonly used acetylcholinesterase inhibitors or "reversal agents" include neostigmine, pyridostigmine, and edrophonium. Despite a similar mechanism of action, the clinical effects (onset, duration, etc.) of these agents differ. Neostigmine and pyridostigmine are hydrolyzed by acetylcholinesterase. During this process, the enzyme is carbamylated and inactivated. Edrophonium does not break down the enzyme acetylcholinesterase. Rather, it competitively and reversibly inhibits its function. The difference in the molecular mechanism of these agents has little impact on clinical use or practice. With these three agents, the peak plasma concentration is achieved at 5 to 10 minutes following bolus administration followed by an elimination half-life of 60 to 120 minutes. Clearance is markedly reduced in the setting of renal failure or insufficiency. There is a marked difference in the onset times of the three reversal agents. The onset of peak effect is 1 to 2 minutes with edrophonium, 7 to 11 minutes with neostigmine, and 16 minutes with pyridostigmine.[102,103] An additional difference is the efficacy of these agents when reversing intense blockade (≥90%), in that neostigmine is more effective.

Adverse effects related to the use of reversal agents generally relate to their inhibition of acetylcholinesterase at sites away from the neuromuscular junction.

These agents should always be preceded by an anticholinergic agent such as atropine or glycopyrrolate since the inhibition of acetylcholinesterase occurs at not only nicotinic receptors (neuromuscular junction) but also muscarinic receptors. Therefore unless preceded by an anticholinergic (antimuscarinic) agent, bradycardia and asystole can occur. The time course of the bradycardic effects varies on the basis of the onset time of the agents (see earlier). As such, if edrophonium is used, glycopyrrolate should be administered first and followed in 1 to 2 minutes by edrophonium given that the onset time of glycopyrrolate is longer than that of edrophonium. The onset time of glycopyrrolate correlates well with that of neostigmine and pyridostigmine, and therefore these agents may be administered at the same time. Given that the onset of atropine is rapid, it may be administered with any of the three reversal agents. Other adverse effects related to the reversal agents included augmentation of cholinergic function in the gastrointestinal tract (salivation, diarrhea, nausea, and vomiting) and the respiratory tract (bronchospasm). Although the anticholinergic agents may block salivation and alterations in airway tone, their efficacy in blocking the increased gastrointestinal motility is somewhat limited.

More recently, there has been development of a novel agent for reversal of neuromuscular blocking agents, sugammadex. In early 2016, this medication was released by the US Food and Drug Administration for clinical use in the United States. Prior to that, it had been approved for use in several countries throughout Europe and the United Kingdom. Sugammadex is a cyclodextrin and instead of inhibiting the enzyme, acetylcholinesterase, it forms a tight 1 : 1 complex with the steroidal neuromuscular blocking agents. It has been shown to rapidly and effectively reverse rocuronium and vecuronium and perhaps even pancuronium.[104,105] There is a limited dissociation rate so that the reversal is maintained. Unlike the use of acetylcholinesterase inhibitors, reversal using sugammadex is feasible even with intense blockade, thereby providing the potential for the rapid reversal of neuromuscular blockade in the "cannot intubate–cannot ventilate" scenario. Future studies are necessary to fully evaluate this medication in the pediatric population.

Monitoring Neuromuscular Blockade

In the operating room, NMBAs may be used as a single dose at the start of the case to facilitate endotracheal intubation or by repeated doses or a continuous infusion to provide ongoing neuromuscular blockade. Some means of monitoring neuromuscular blockade is necessary since administration of excessive doses may mandate the use of postoperative mechanical ventilation until neuromuscular blockade has worn off or can be reversed. Additionally, given concerns regarding prolonged paralysis, monitoring neuromuscular function may also be considered in the PICU setting.

Monitoring may include some combination of visual, tactile, or electronic means of measuring the residual neuromuscular function following electrical stimulation. The technique, most commonly used by anesthesiologists in the operating room to monitor the degree of neuromuscular blockade, is peripheral nerve stimulation or TOF monitoring. TOF monitoring involves placement of standard electrocardiographic electrodes over a peripheral nerve. The nerves most commonly

used are the facial, ulnar, or common peroneal, which result in corresponding movement in the muscles of the hand, face, or leg. In some circumstances, direct stimulation of the muscle may occur, giving the false impression that an appropriate amount of neuromuscular blockade has not been achieved. To avoid such problems, it may be appropriate to place the TOF monitor and assess the twitch response before the administration of the initial dose of the NMBA. The electrodes of the TOF monitor are connected to a handheld peripheral nerve stimulator, which delivers two stimuli per second at 50 mA for 2 seconds. A total of four stimuli are administered over 2 seconds—hence the term *train-of-four.* As this is painful, it should only be performed in patients that are anesthetized or sedated. Depending on the number of acetylcholine receptors that are occupied by the nondepolarizing NMBA, there will be anywhere from zero to four responses or twitches. Despite the availability of other more sophisticated machines to monitor the degree of neuromuscular blockade in the operating room and ICU setting, these monitors are generally used only for clinical research purposes. In clinical practice in either the operating room or PICU, TOF monitoring remains the technique that provides the most useful information with limited requirements for training and equipment.

In clinical practice, the TOF monitoring is combined with clinical assessment at the end of the case to ensure that the patient is strong enough for extubation. Following reversal of neuromuscular blockade, clinical assessment of strength is combined with neuromuscular monitoring. These latter measures become necessary as residual weakness may be present despite apparent reversal using TOF monitoring. Techniques of clinical assessment to evaluate the presence of residual neuromuscular blockade include measurement of negative inspiratory force (NIF) or maximum inspiratory pressure (MIP), hand grip, or head lift. Although head lift and hand grip require the ability to follow a simple command, the measurement of NIF does not. The technique involves measuring the inspiratory force that the patient can generate against an occluded airway. The test can be completed with a simple manometer attached to the 15-mm adaptor of the ETT. Initial studies suggested that a NIF of at least −20 cm H_2O indicated sufficient muscle strength to maintain an adequate minute ventilation.[106] Subsequently, a value of −25 to −30 cm H_2O became the generally accepted value for use in clinical practice. However, subsequent work suggested that although strength was adequate to maintain minute ventilation, it may not be adequate to maintain upper airway patency. Therefore the use of voluntary responses (head lift for 5 seconds or hand grip) was suggested as an adjunct to ensure adequate reversal of neuromuscular blockade.[81] In infants, reflex leg lift (both legs lifted off of the operating room table) was shown to correlate with a mean NIF or MIP of −51 cm H_2O, so the authors concluded that this was a sign of adequate reversal of neuromuscular blockade in infants.[107] Given the variability of these responses and their correlation with reversal of neuromuscular blockade, the best clinical approach may be the use of several clinical maneuvers if TOF monitoring is not available. The literature suggests that the ability to maintain a sustained head lift for 5 seconds is the most sensitive clinical tool.[101]

In the ICU setting, given the degree of neuromuscular blockade that is induced, voluntary measures of muscle strength are not adequate. Therefore titration of NMBAs should be guided by the use of TOF monitoring. The technique may allow the use of the lowest possible dose of agents and theoretically avoid complications

such as prolonged blockade (see later). In a prospective randomized trial in 77 adults, TOF monitoring (maintaining one twitch of the TOF) was compared with clinical parameters (patient breathing over the preset ventilator rate) as a means of titrating NMBAs.[108] TOF monitoring resulted in a lower total dose and lower average infusion rate of vecuronium, as well as a more rapid recovery once the infusion was discontinued. A subsequent study in adults revealed a decreased incidence of persistent neuromuscular weakness when using TOF monitoring.[109]

Although data are lacking to clearly demonstrate the superiority of TOF monitoring in the PICU setting, its use is suggested as a means of titrating the administration of NMBA agents. Of note are the significant interpatient variability that has been reported in the PICU setting and the inability to therefore ensure an appropriate dose without some monitoring modality. The choice of the number of twitches to maintain has not been prospectively studied. The majority of the clinical evidence suggests that maintaining one twitch of the TOF ensures an adequate degree of neuromuscular blockade while potentially limiting the incidence of persistent neuromuscular weakness. However, the least amount of blockade that can be clinically tolerated is suggested. In some patients, maintaining two twitches may be acceptable, especially with the use of an appropriate degree of sedation and analgesia. When TOF monitoring is not in use or is not feasible, "drug holidays" are commonly employed where the NMBA agent is temporarily discontinued until some clinical sign of neuromuscular function such as motor movement is noted. At that time, if needed, the infusion is restarted or an additional bolus is administered.

No study has evaluated the best nerve (facial, ulnar, common peroneal) to monitor. In clinical practice, any accessible nerve can be used. However, several patient and technical factors may affect the response. As such, whenever feasible, placement of the monitor before the institution of neuromuscular blockade is suggested to ensure that a TOF can be obtained before the administration of the NMBA. If no response is obtained, the technique should be evaluated by first evaluating the monitor (faculty monitor, electrodes, or batteries). Is the electrode too far from the nerve (improper placement, edema, obesity)? If these technical problems are ruled out, the infusion can be decreased by 10% to 15% and the TOF measured again in 2 hours. When two or more twitches are noted, if the patient is stable and a more profound degree of blockade is not required, ongoing observation is suggested. If a deeper level of blockade is required, a bolus equivalent to the hourly infusion rate should be administered and the infusion increased by 10% to 15%.

Adverse Effects of Neuromuscular Blockade

As with any medication used in the PICU patient with comorbid diseases, adverse effects may occur with NMBAs. Perhaps the most devastating of these adverse effects is the inability to provide adequate ventilation following the administration of a medication that induces apnea. Therefore these medications should never be used if there is any suspicion that the airway cannot be controlled. In rare circumstances, endotracheal intubation using direct laryngoscopy may be impossible. In even rarer circumstances, adequate bag-mask ventilation cannot be provided. In such scenarios, death or permanent CNS morbidity will result with the administration of NMBAs. Measures to avoid such problems include an assessment of the airway before the administration of these agents and knowledge of the

“cannot intubate–cannot ventilate” algorithm as outlined by the American Society of Anesthesiologists.

Various physical characteristics may suggest that direct laryngoscopy and endotracheal intubation will be difficult including micrognathia, a short neck, limited neck mobility (flexion/extension), limited mouth opening, a large tongue, and a small mouth. An additional tool is the Mallampati grade, which describes the ability to visualize the tip of uvula and the tonsillar pillars.[110,111] If there is a suspicion that endotracheal intubation using direct laryngoscopy will not be possible and there is time, other techniques to control the airway are suggested. Some of the more commonly used approaches to the difficult airway in infants and children are described elsewhere.[112] The techniques needed for the “cannot intubate–cannot ventilate” scenario should be understood and available in any situation in which NMBAs are being administered. This should include alternative options for endotracheal intubation including repositioning the patient or using a different type of laryngoscope including indirect laryngoscopy, such as the Glidescope.[110,111] Physicians using NMBAs should also have a working knowledge of the laryngeal mask airway as it can be used to rescue patients when laryngoscopy, endotracheal intubation, and bag-valve-mask ventilation fail.[113]

Other adverse effects from NMBAs relate to the elimination of protective physiologic functions. Eye care with the use of artificial tears or Lacri-Lube at fixed intervals during the administration of NMBAs is necessary to avoid drying and damage to the cornea. Repositioning of the patient at frequent intervals is necessary to avoid pressure sores. For prolonged immobility, the use of special mattresses may be considered as an adjunct to frequent patient moving. Passive range of motion may also be implicated with splinting to prevent forearm and ankle contractures while sequential compression devices may be indicated to prevent deep vein thrombosis. Ineffective coughing and clearance of secretions mandate the implication of suctioning protocols to limit the risk of nosocomial pneumonias. Alterations in normal physiologic respiratory parameters include a decrease in functional residual capacity, increase in dead space, and ventilation-perfusion ratios that may result in ventilatory issues including hypoxemia or hypercarbia and the need to adjust ventilatory parameters.

Although these agents prevent movement, they provide no degree of sedation or analgesia. As such, monitoring sedation using clinical scoring systems is generally not feasible. Therefore some other measure of the depth of sedation may be required. In the majority of clinical situations, physiologic parameters such as heart rate and blood pressure are used as a means of titrating sedative and analgesic agents. However, issues arise in critically ill patients in whom alterations in heart or blood pressure may not occur in response to stress or pain. In this patient population, exogenous vasopressors may be in use and thereby eliminate the reliability of physiologic parameters. In the operating room setting, the availability of depth of anesthesia monitors is recommended and it is suggested that their use be considered in patients at high risk for awareness. Despite the rare occurrence of such events, means for their prevention of awareness during the use of neuromuscular blocking agents in the PICU appear indicated given the consequences of such problems.

In the operating room setting, various depth of sedation or anesthesia monitors are currently available. To date, there are no data in the PICU to demonstrate their efficacy in preventing recall during the use of neuromuscular blocking agents. The

bispectral (BIS) index is a processed electroencephalographic parameter expressed as a numeric value ranging from 0 (isoelectric electroencephalogram) to 100 (awake, eyes open, no sedative agent). In the pediatric population, its intraoperative use has been suggested to decrease the incidence of awareness.[114] In the PICU population, the BIS value has been shown to generally correlate with the depth of sedation assessed using various clinical scoring systems.[115,116] In one such study, BIS monitoring was used to evaluate the depth of sedation in a cohort of 12 PICU patients receiving NMBAs.[117] BIS monitoring was used for a total of 476 hours and revealed that the desired depth of sedation (BIS number 50 to 70) was achieved 57% of the time. The BIS number demonstrated a deeper than desired depth of sedation (BIS number ≤49) 35% of the time and an inadequate depth of sedation in patients receiving neuromuscular blockade (BIS number ≥71) 8% of the time. At the time that additional sedation was administered by the bedside nurse who was not allowed to view the monitor, the BIS number was 71 or greater 64% of the time; 50 to 70 during 31% of the time, and 49 or less 5% of the time. Although no long-term follow-up or assessment of awareness was pursued, the authors concluded that physiologic parameters are not a viable means of assessing the depth of sedation during the use of NMBAs.

The adverse effect that has received the most attention in the adult population with the administration of NMBAs is residual neuromuscular paralysis. In clinical practice, it appears that there are two distinct entities that may account for prolonged neuromuscular paralysis: (1) prolonged recovery from neuromuscular blockade related to excessive dosing or delayed clearance of the parent compound or metabolites due to renal or hepatic issues and (2) what is now termed the *acute quadriplegic myopathy syndrome* (AQMS).[118-121] Potential concern of such problems was first reported in 1992 with the use of vecuronium in patients with renal insufficiency.[118] Problems related to excessive dosing or inadequate clearance of an active metabolite generally resolve spontaneously over time with clearance of the parent compound or its metabolites. In clinical practice, prolonged recovery is defined as a recovery time of more than 100% of the predicted parameter. In distinction, AQMS presents with acute paresis, myonecrosis with increased plasma markers demonstrating muscle breakdown such as creatinine phosphokinase (CPK), and abnormal electromyography (EMG) with the demonstration of reduced compound motor action potential amplitude, decreased motor nerve conduction, and evidence of acute denervation. Clinical findings include flaccid paralysis, relative preservation of extraocular movements, decreased deep tendon reflexes, respiratory insufficiency, intact sensory function, and normal findings in the cerebrospinal fluid.[119-121] Recovery may require weeks to months, with the need for prolonged rehabilitation care, and tracheostomy with chronic ventilatory support, all of which may significantly affect the cost of ICU care. Although initially reported only with aminosteroid compounds, it has been subsequently also reported with the benzylisoquinolinium derivatives.[122,123]

Given that CPK values are elevated in up to 50% of patients with AQMS, periodic screening of patients receiving ongoing neuromuscular blockade may be indicated. As problems have been noted more commonly following the prolonged, continuous infusion of NMBAs, it has also been suggested that drug holidays or periodic interruption of the infusion be considered. However, there are no data to demonstrate that such practice will alter the incidence of AQMS and even the

periodic withdrawal of neuromuscular blockade must be considered on a risk-benefit ratio. Termination of the use of NMBAs is suggested whenever it is clinically feasible given their adverse effect profile. Other factors and comorbid processes that may contribute to the development of AQMS include nutritional deficiencies; coadministration of other medications (cyclosporine, corticosteroids, aminoglycosides); hyperglycemia; hepatic or renal insufficiency; and electrolyte disturbances. The association is most profound with the coadministration of NMBAs and corticosteroids, thereby suggesting a heightened awareness in such patients.[122] In addition to AQMS, other conditions to consider in the differential diagnosis of patients with prolonged weakness following the use of NMBAs include neuromuscular conditions (myasthenia gravis, Eaton-Lambert syndrome, Guillain-Barré syndrome); acquired or primary myopathic conditions (mitochondrial myopathy, steroid myopathy); central nervous system injury; spinal cord injury; critical illness polyneuropathy; disuse atrophy; and electrolyte or metabolic disturbances. Critical illness polyneuropathy may be confused with AQMS. It is a combined motor and sensory neuropathy that results from ischemia of the microvasculature of the nerves, which is seen most commonly in patients with multisystem organ failure. EMG demonstrates a pattern different from that seen in AQMS.

Summary: Neuromuscular Blocking Agents in the PICU

In addition to their use in the operating room, specific situations that mandate the use of neuromuscular blocking agents in the PICU may arise (Table 133.1). Although these agents are generally administered as intermittent bolus doses in the operating room, in the PICU, a more stable baseline level of neuromuscular blockade may be desired and therefore a continuous infusion may be used. When choosing an agent for use in the PICU population, the major issues include cardiovascular effects, metabolism, and cost. Because many of the patients in the PICU have some degree of hemodynamic instability, agents that cause excessive histamine release should be avoided. Additionally, the presence of hepatic or renal insufficiency may affect metabolism or elimination or the parent compound, as well as its metabolites. In the absence of end-organ dysfunction, pancuronium offers an inexpensive means of achieving neuromuscular blockade. Its vagolytic effect will result in tachycardia with an increase in heart rate of 10 to 20 beats per minute above baseline. Given its duration of action, intermittent dosing is feasible. With its availability in generic form, vecuronium provides another cost-effective option in the PICU setting while eliminating the tachycardia that is seen with pancuronium. Although vecuronium and pancuronium are generally effective and inexpensive in patients without end-organ dysfunction, significant alterations in infusion requirements occur in patients with renal insufficiency/failure (pancuronium and vecuronium) or hepatic insufficiency/failure (vecuronium). Atracurium or cis-atracurium may be a more appropriate choice in patients with hepatic or renal failure because such problems do not alter dosing requirements of either agent.[124]

In the PICU setting, like the operating room, adjustment of the dose based on monitoring with a peripheral nerve stimulator is recommended. Regardless of the

agent used, significant interpatient variability with up to 10-fold variations in infusion requirements may be noted. The variability results from not only interpatient variability but also various associated conditions that may increase or decrease the sensitivity to NMBAs (Tables 133.6 and 133.7). On the basis of this knowledge, the recommended doses (Table 133.8) for the various NMBAs are starting guidelines and the infusion should be increased or decreased as needed to maintain one twitch of the TOF or provide the required depth of neuromuscular blockade. An additional problem that occurs in the ICU patient who receives NMBAs for a prolonged period of time is the development of tachyphylaxis or an increased dose requirement over time. The primary cause is an upregulation of acetylcholine receptors in patients who are chronically exposed to NMBAs. Dodson et al.[125] demonstrated an increased density of acetylcholine receptors in muscle from patients who had received prolonged infusions of NMBAs. Prolonged neuromuscular blockade like partial or complete deafferentation leads to proliferation of acetylcholine receptors at the neuromuscular junction. This problem requires that the dose of the NMBA be increased over time to maintain the same amount of neuromuscular blockade.

TABLE 133.6

Factors That Increase Sensitivity to Neuromuscular Blocking Agents

Medications:
______inhalational anesthetic agents
______local anesthetic agents
______antibiotics (aminoglycosides)
______antiarrhythmic agents (quinidine, procainamide)
______calcium channel blockers
______beta-adrenergic antagonists
______chemotherapeutic agents (cyclophosphamide)
______diuretics (furosemide)
______dantrolene
______lithium, magnesium
______cyclosporin
Underlying disorders:
______electrolyte disturbances (hypokalemia, hypermagnesemia, hypocalcemia)
______hypothermia
______respiratory acidosis
______metabolic alkalosis
______myasthenia gravis
______Eaton-Lambert syndrome
______muscular dystrophy
______multiple sclerosis
______amyotrophic lateral sclerosis
______poliomyelitis

TABLE 133.7
Factors That Decrease the Sensitivity to Neuromuscular Blocking Agents
Medications: ______anticonvulsant agents (phenytoin, carbamazepine) ______aminophylline Underlying conditions: ______hypercalcemia ______burns ______prolonged administration of neuromuscular blocking agents

TABLE 133.8

Suggested Starting Guidelines for the Continuous Infusion of Neuromuscular Blocking Agents

Agent	Dose	Comments
Pancuronium	0.06-0.08 mg/kg/h	Vagolytic effect, primary renal excretion
Vecuronium	0.1-0.15 mg/kg/h	No cardiovascular effects, hepatic metabolism to active metabolites, which are renally excreted
Rocuronium	0.6-0.8 mg/kg/h	Mild vagolytic effect, hepatic metabolism
Atracurium	1-1.5 mg/kg/h	Mild histamine release, non–organ-dependent elimination
Cis-atracurium	0.2 mg/kg/h	No cardiovascular effects, non–organ-dependent elimination

Given their adverse effect profile, it is recommended that NMBAs be administered only when aggressive attempts at sedation have failed to provide the desired level of patient immobilization. An ongoing assessment regarding the need for continuing such therapy is suggested with discontinuation of the medication as early as is feasible. Specific protocols should be in place to ensure appropriate care of the patient who is receiving neuromuscular blockade with attention toward the provision of adequate sedation and analgesia, eye care, prevention of pressure sores, and pulmonary toilet.

CHAPTER 134

Sedation and Analgesia

Christopher M.B. Heard, Omar Al Ibrahim

PEARLS

- A wide selection of sedation and analgesia options is available in the pediatric intensive care unit.
- No ideal sedative agent exists for all patients.
- Most children do well with a combination of opiates (fentanyl or morphine) and supplementation with benzodiazepines either by infusion (midazolam) or on an as-required basis (lorazepam) to provide adjunct anxiolysis and amnesia.
- Postoperatively, patients require adequate analgesia, which may include the use of epidural anesthesia or patient-controlled analgesia.
- When the ability to perform a rapid neurologic examination is required, use of short-acting agents such as remifentanil, propofol, or isoflurane may be warranted.
- All sedative agents result in tolerance with prolonged use. The intensive care physician must be aware that withdrawal may occur with the prolonged use of these agents (ie, more than 3 to 5 days).
- A proactive treatment plan with methadone at the equivalent dose can effectively and safely prevent opiate withdrawal in the patient in the pediatric intensive care unit.

Sedation is an integral part of patient management in the pediatric intensive care unit (PICU). It is necessary to minimize the perception of and response to anxiety and pain. Children who are not adequately sedated or who are experiencing pain may become tachycardic and hypertensive. They also may become agitated and as a result endotracheal tubes and central lines may become dislodged. Adequate sedation and analgesia also facilitates bedside nursing and respiratory care, and it prevents dislodging of critical tubes and monitoring devices like central venous lines, arterial lines, chest tubes, and endotracheal tubes. Optimizing sedation and analgesia has been shown to reduce oxygen consumption in critically ill children and modulate the intensity of stress inflammatory response. Conversely, oversedation can cause cardiovascular depression and ileus and may interfere with a comprehensive neurologic examination. In patients who undergo prolonged sedation, tolerance and tachyphylaxis develop, which lead to increasing sedative

requirements.

Patients may recall their stay in the ICU. Many patients remember having an endotracheal tube or having their lungs mechanically ventilated. Nightmares and hallucinations also have been reported.[1] Either single-drug therapy or inadequate dosing may be associated with a heightened incidence of recall in the patient receiving neuromuscular blocking agents.[2] In adults, delusional memories and an underlying anxiety state were predictors of the development of posttraumatic stress disorder after sedation in the ICU.[3] Delusional memories were reported much more frequently than factual memories, probably because most patients have difficulty correctly remembering the events that occur during their stay in the ICU. In pediatric patients, recall of the PICU experience also has been reported.[4] More than 66% of pediatric patients remembered their stay in the PICU. Eighteen percent had bad memories, 16% remembered mechanical ventilation and anxiety, and 29% remembered pain from a procedure or movement. Overall the recollections of patients in the PICU were considered negative in approximately 15% of the patients. Sleep disturbance also was a problem.

Posttraumatic stress disorder (PTSD) is a possible complication of a child's stay in the ICU. Several components are required for the diagnosis of PTSD.[5] The American Psychiatric Association's *Diagnostic and Statistical Manual*, Fifth Edition (DSM-V) requires the following criteria for a diagnosis of PTSD in adults, adolescents, and children older than 6 years: (1) an exposure, (2) one or more intrusion or reexperiencing symptoms, (3) avoidance behavior, (4) and alterations in arousal associated with the traumatic event (D); in addition, the symptoms should (5) have exceeded 1 month (6) and have a clinically significant effect on the child's functioning. There is no specific test for PTSD, but children often have a low basal cortisol level, with exaggerated cortisol suppression in response to dexamethasone.

Using a slightly modified alternate DSM criterion, which has been shown to be more appropriate criteria for children (Table 134.1), the incidence of PTSD in children[6] aged 6 through 16 was 29%. There appeared to be no difference in the incidence with respect to age; however, younger children tended to have more avoidance of thoughts, whereas older children suffered from diminished interest in activities and difficulty concentrating. This is important, as these findings could persist for up to 6 months and affect the daily function of the child and family after discharge. It is important to ensure that children are suitably sedated and receiving appropriate analgesia during their ICU stay.

TABLE 134.1

Posttraumatic Stress Disorder Alternative Algorithm

Criterion A (Event)
Experienced event that threatened death or serious injury
Criterion B (Reexperiencing)
Recurrent distressing memories
Recurrent distressing dreams
Sense of reliving events
Psychologic distress with reminders
Physiologic reactivity with reminders

Criterion C (Avoidance)
Avoidance of thoughts, feelings
Avoidance of activities
Diminished interest in activities
Detached from others
Restricted affect
Sense of foreshortened future
Criterion D (Hyperarousal)
Difficulty sleeping
Irritability/anger
Difficulty concentrating
Hypervigilance
Exaggerated startle response
Criterion E (Duration)
Duration greater than 1 month
Criterion F (Effect)
The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

Various scoring systems are often used to guide sedation. The most widely used is the Ramsay scale.[7] The patient's level of consciousness is given as one of six scores (Table 134.2). The nurse at the bedside assesses the patient and then changes the sedation regimen as necessary to achieve the desired level of sedation. The ideal level of sedation varies from patient to patient, but in general, most intensive care physicians seek to maintain patients in a sleepy but easily awakened state. A Ramsay score of 2 to 3 seems to be ideal as the clinical end point for sedation. Deeper sedation should be reserved for select patients who are often younger, are receiving neuromuscular blocking agents, or have a head injury. The use of a sedation scoring system to guide sedation of surgical critical care patients has been evaluated for cost effectiveness. The use of scoring systems has been proved to save costs in the ICU.[8] Because the patient can be weaned more rapidly from the ventilator through better control of the sedation level, the number of days a patient is connected to a ventilator is reduced. The Comfort score, which is composed of eight variables (each with five categories), also has been validated for use in the PICU to assess sedation level in children. Use of this system, however, is more complicated and time consuming.[9]

TABLE 134.2

Ramsay Scale

Level	Description
1	Patient awake, anxious, and agitated, restless, or both
2	Patient awake, cooperative, oriented, and tranquil
3	Patient awake, responds to command only
4	Patient asleep, brisk response to light glabellar tap or loud auditory stimulus
5	Patient asleep, sluggish response to light glabellar tap or loud auditory stimulus
6	Patient asleep, no response to light glabellar tap or loud auditory stimulus

Many scoring systems are subjective and are limited by interobserver variability.

The more objective methods may be too cumbersome for routine use. A simple scoring system has been devised that is easy to use and minimizes subjectivity and observer variability.[10] This system is the Brussels sedation scale. It is similar to the Ramsay scale, but the Brussels scale levels that correspond to the Ramsay scale levels 4 and 5 are better differentiated (Table 134.3).

TABLE 134.3

Brussels Sedation Scale

Level	Description
1	Unable to be aroused
2	Responds to painful stimulation (trapezius muscle pinching) but not auditory stimulation
3	Responds to auditory stimulation
4	Awake and alert
5	Agitated

The Bispectral Index (BIS) is a processed electroencephalogram (EEG) monitor that measures the hypnotic effects of anesthetics and sedatives. The BIS is an empirical, statistically derived measurement. The BIS monitor reports a single number from 0 to 100 that represents an integrated measure of cerebral electrical activity. The BIS has been validated as a measure of hypnosis in adults in the operating room and ICU.[11] More recently it has been validated in the PICU.[12] The BIS is an exciting new approach to EEG processing. It measures a state of the brain, representing the degree of alertness. It does not measure the concentration of a particular drug.[13] A number of 100 on the BIS score indicates that the patient is fully awake, whereas a number less than 40 suggests a deep hypnotic effect. A BIS value of less than 60 in surgical patients was not associated with a recall of intraoperative events.[14] The use of the BIS monitor in adult surgical patients and in older pediatric patients has shown a reduction in anesthesia requirements and a shorter recovery time. The BIS monitor has been studied in several adult ICU populations. These studies have shown a correlation between the BIS score and a variety of sedation scores.[15]

One of the main difficulties with clinical sedation scoring systems is their inability to assess depth of sedation in the patient receiving neuromuscular blocking agents (NMBAs). Patients who require NMBAs in the operating room are considered to be at an increased risk of awareness during anesthesia.[16] This problem also exists for the sedated patient with paralysis in the PICU. It is well known that the clinical signs of inadequate anesthesia or sedation are not reliable[17] and that there are many other reasons for alterations in the heart rate, blood pressure, perfusion, and pupillary responses in the PICU patient. In a study using the BIS in pediatric patients with paralysis,[18] researchers found that in more than 8% of the sedation assessments in which patients were thought to be adequately sedated by the bedside nurse, the patients' BIS scores were greater than 80 (Fig. 134.1). This score reflected a significant risk of awareness. The BIS correlates well with the Ramsay scale in the sedated child and may be a useful monitor to prevent inadequate sedation in a child with paralysis.

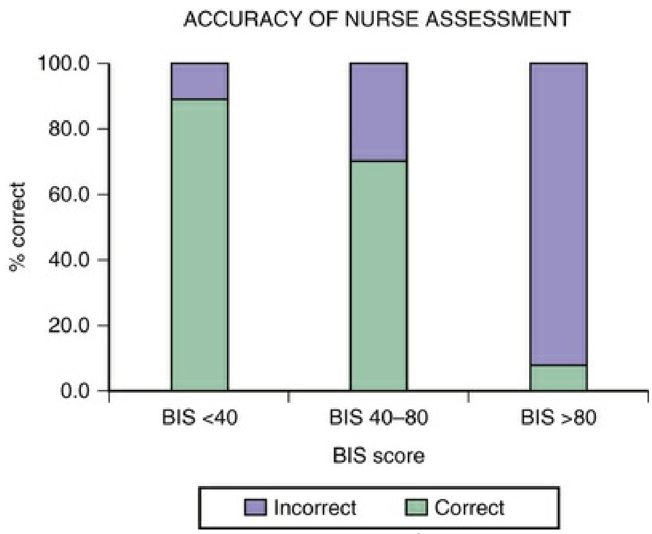

FIG. 134.1 Nurse sedation assessment of the paralyzed patient. *BIS*, bispectral index.

An important aspect of sedation monitoring is the level of stimulus. The BIS monitor will estimate the degree of hypnosis at a point in time in the context of the balance between sedation, analgesia, and stimulation. It cannot predict what will happen if this balance is changed. A comparison of the Comfort score to the BIS monitor demonstrates this effect. Using the Comfort score, the majority of patients were considered oversedated at baseline (score <11). The BIS assessment at the same time demonstrated that the majority of the patients were appropriately sedated (BIS 40-80). When the child was stimulated (tracheal suctioning), the majority of the Comfort scores were now appropriately sedated, as were the BIS scores. The BIS scores rose from a mean of 52 to a mean of 60. What is unclear is whether the Comfort score or the BIS was a better assessment tool, questioning if the children oversedated without stimulation should be kept lighter and sedated only for procedures?

Although the BIS monitor is used in many institutions, the question of whether its use can prevent awareness under anesthesia is still debated. One study enrolled 2000 adults whose anesthesia was titrated to a BIS score of lower than 60 or by the end-tidal inhalational concentration of the anesthetic agent to at least 0.7 minimum alveolar concentration (MAC).[19] Postoperatively all patients were interviewed to assess their intraoperative awareness. This study found two cases of awareness in each group. The MAC values in both groups were the same. The BIS was greater than 60 in one case of awareness. Although the BIS monitor was not able to reduce this low incidence of awareness, the level of anesthesia between the groups was very similar. This study was severely underpowered to show any benefit. However, the combination of end-tidal monitoring and BIS monitoring may help to reduce intraoperative awareness.

Another potential concern with using the BIS monitor is its relevance or reliability for the pediatric patient. Research thus far showing a correlation with the myriad of sedation scoring systems used in the PICU is limited by the limitations of these scoring systems. Furthermore, the lack of continuous sedation assessment by these scoring systems, as is possible with BIS monitoring, makes comparison difficult. Also of concern is whether the EEG analysis algorithms used in the BIS monitor are applicable to the pediatric brain. This issue needs further evaluation before the BIS

monitor can be considered a standard in the PICU. Pediatric-specific BIS probes are now available. The possible inaccuracy of the BIS in younger children has been demonstrated in the operating room, where BIS numbers in younger children (age 1-12 years) tended to be higher (>60) than in older children receiving the same propofol, remifentanil-based anesthetic.[20] In this study there was no recovery benefit to a BIS-driven anesthetic compared to a standard dose-based, clinical signs anesthetic. In fact, the younger children took longer to wake up due to high doses of sedation agents given in an effort to keep the BIS <60. The children with the BIS >60 appeared to be appropriately anesthetized, and as such, the concept that the BIS must be less than 60 to ensure adequate anesthesia in younger children may not be correct. This may correlate with the need to select a different BIS end point in the PICU also. Finally, a limitation of the BIS monitor is that it is less reliable when used with certain hypnotic agents such as ketamine, dexmedetomidine, nitrous oxide, xenon, and opiates.

Other processed EEG sedation assessment monitors are now available. The SNAP II monitor[21] uses a different spectrum of EEG frequency analysis. Little difference between the BIS and the SNAP II monitors has been shown thus far. Currently, little experience has been reported with the SNAP II monitor in pediatric patients. In the PICU, the SNAP was found not to correlate well (r = 0.18) with the sedation depth of intubated children. The mean SNAP index changed only between 58 and 68 over a sedation score reflecting deep to light sedation.[22]

Opioids and Analgesia in the Pediatric Intensive Care Unit

Sedation in the PICU is most commonly achieved with a mixture of opioids and benzodiazepines (BZDs). Although many synthetic and naturally occurring opioids exist, morphine is considered the agent against which others are compared. The primary source of morphine is opium obtained from the opium poppy (*Papaver somniferum*), which also produces alkaloids such as codeine, thebaine, papaverine, and noscapine. Opiates are substances derived from opium; the term *opioid* also describes substances derived from opiates (eg, oxycodone) but includes substances that are created synthetically but have properties that are similar to those of opiates (eg, fentanyl and methadone) and endogenous ligands. The terms often are used interchangeably because the pharmacologic effects fall into the same category. Opioids are agonists at various opioid receptors, for which several endogenous ligands exist. There are three major classes of receptors: mu (μ), kappa (κ), and delta (δ). The opioid receptors possess the same general structure of an extracellular N-terminal region, seven transmembrane domains, and an intracellular C-terminal tail structure. Subtypes of each receptor (eg, μ_1, μ_2) exist (Table 134.4), as do less well-characterized opioid receptors ε, Δ, τ, and ε.

TABLE 134.4

Classification of Opiate Receptors and Subtypes

Subtype	Prototypic Drugs	Actions
Mu_1	Opiates and most opiate peptides	Supraspinal analgesia including periaqueductal gray matter, nucleus raphe magnus, and locus coeruleus

		Prolactin release
		Acetylcholine turnover in brain
		Catalepsy
Mu_2	Morphine	Respiratory depression
		Dopamine turnover in brain
		Gastrointestinal tract transit
		Most cardiovascular effects
Delta	Enkephalins	Spinal analgesia
		Dopamine turnover
Kappa	Dynorphin	Spinal analgesia
		Inhibition of antidiuretic hormone
		Sedation
Sigma	N-allynormetazocine	Psychotomimetic effects

Modified from Baresh PG, Cullen BF, Stoelting RK et al., eds. Clinical Anesthesia. 2nd ed. Philadelphia: JB Lippincott: 1992.

Most of the therapeutic and adverse effects can be accounted for by agonist activity at the μ-receptor, which is responsible for analgesia, respiratory depression, pupillary constriction, and euphoria. At the cellular level, μ-receptor activation alters ionic permeability to K^+, causing hyperpolarization and depression of excitability in the nervous system. Associated effects on cholinergic, adrenergic, serotonergic, and dopaminergic neurotransmitter systems are seen within the central nervous system (CNS). These receptors are found at multiple sites along pain pathways including the spinal cord, midbrain, thalamus, and cortex. At the spinal cord level, pain reflexes (nociceptive) are depressed by receptors in the substantia gelatinosa, which are mostly presynaptic and inhibit the release of substance P from C-fiber nerve terminals and account for the effectiveness of intrathecally and epidurally administered opioids. In the midbrain the analgesic effect is mediated in the periaqueductal gray matter through ascending fibers and also descending fibers that modulate the function of the dorsal horn. Acetylcholine, γ-aminobutyric acid (GABA), norepinephrine, and serotonin also are involved in these pain-modulating pathways. Peripheral opioid receptors also have been shown and can be expressed in response to inflammation.[23] The intraarticular injection of morphine produces analgesia following arthroscopy through activation of opioid receptors located on white blood cells.[24]

The endogenous ligands for the opioid receptors are the enkephalins, endorphins, and dynorphins. They have a morphine-like effect that can be specifically antagonized by the μ-receptor antagonist naloxone. The endomorphins have potent analgesic and gastrointestinal (GI) effects. At the cellular level, they activate G proteins ([35S] GTP gamma-S binding) and inhibit calcium currents.[25] Pro-opiomelanocortin is the precursor for β-endorphin (as well as adrenocorticotropic hormone and melanocyte-stimulating hormone). β-Endorphin, itself very active, also includes the amino acid sequence for met-enkephalin, although the main precursor is proenkephalin A, which contains four copies of met-enkephalin and one copy of leu-enkephalin. The met-enkephalin sequence also gives opioid activity to a number of other larger peptides. Proenkephalin B (prodynorphin) gives rise to the dynorphin series and contains three leu-enkephalin sequences. Local application of these endogenous substances to the brain provides effects that are similar to those of opiates. They arguably do not function as analgesics in basal states, because the administration of naloxone does not cause pain in the normal state. They are released during periods of sustained pain, stress, or activity to modulate physiologic pathways, including those involved with pain. Therefore they are probably

important to the physiologic condition of the patient in the ICU.

Specific Opioid Agonists

Morphine

Morphine is an opiate, and its primary therapeutic actions are sedation and analgesia; anxiolysis and euphoria also may occur. These four therapeutic effects may be exploited to the benefit of the patient. These actions are mediated through the periaqueductal gray matter, the ventromedial medulla, and the spinal cord. The reduction of nociceptive reflexes occurs all over the body, even below a completely transected spinal cord. In addition to increasing the sensory threshold for pain, morphine may decrease the hurting aspect (or unpleasantness) of pain. A patient given morphine may say something such as “I have just as much pain, but it doesn't distress me as much.” It blunts most types and intensities of pain, although some forms of neuropathic pain are relatively resistant. The resulting analgesia may be potent enough to abolish diagnostic symptoms and signs. The sedative effects reduce higher cortical function, cause difficulty in concentration, and cause a sense of drowsiness and dream-filled sleep. Higher doses will cause a state of unconsciousness or coma. The rate of respiration is reduced with a resultant fall in minute ventilation despite an accompanying increase in depth of breathing. This effect is associated with a decreased responsiveness to carbon dioxide (CO_2) and is additive to the decreased CO_2 response seen during sleep. In some circumstances respiratory drive may be limited to hypoxic stimulation of the carotid chemoreceptors; this is the most serious dose-related adverse effect of morphine. It can occur at doses used clinically for analgesia. In general, all opiates produce the same degree of respiratory depression when given in equipotent doses and for any given level of analgesia. Opioids do not have anticonvulsant properties, whereas meperidine (and its metabolite normeperidine) may lower the seizure threshold.

Another CNS effect of morphine is pupillary constriction due to a central effect on the oculomotor nucleus. Nausea results from stimulation of the chemotrigger zone; however, opioids also depress the vomiting center, so the final effect is unpredictable. Nausea and vomiting are much more frequent in ambulatory patients than in patients confined to a hospital bed. Morphine can modify stress-related endocrine responses. It decreases the release of several hormones including adrenocorticotropic hormone, antidiuretic hormone, prolactin, growth hormone, and epinephrine. The neuroendocrine stress response that is normally seen with trauma and surgery may be blunted. Itching may be caused by histamine release, but it also may be due to opiate receptor activation in the spinal cord.[26]

Morphine's effects on smooth muscle cause constipation. It reduces the intestinal propulsion activity through its central and peripheral effects. The central effects may be mediated by the vagus nerve. The direct smooth muscle relaxation and the increased local cholinergic transmission can be partly reversed by naloxone. This decreased motility is the basis of several over-the-counter antidiarrheal preparations including diphenoxylate, a μ-agonist that does not cross the blood-brain barrier and thus acts as a peripheral opioid agonist. Morphine also causes an increase in biliary tract tone, which may cause biliary colic, as well as increased tone in the bladder detrusor muscle and vesical sphincter. Urinary retention is common with opioids

and occurs in 55% of children receiving spinally administered opioid and 20% receiving intravenous (IV) opioid.[27]

Morphine has been studied extensively in term and preterm neonates. Glucuronidation is present in term babies and in many preterm ones. The half-life of morphine, however, is 2 hours in children, 6.5 hours in term neonates, and 9 hours in the preterm child because of reduced clearance. Volume of distribution does not vary with age.[28] Morphine causes histamine release and can cause peripheral vasodilatation. Infused at analgesic doses, it has little effect on the cardiovascular system, but skin flushing is not uncommon with rapid IV administration. The histamine-releasing potential should be considered in patients with asthma, especially during an acute exacerbation, and in patients with unstable cardiovascular systems for whom safer alternatives, such as fentanyl, exist.

Dosing recommendations in the ICU include a bolus dose of 0.05 to 0.1 mg/kg and an infusion of 0 to 30 μg/kg/h. Fifty percent of these doses should be used if the patient is younger than 3 months of age. The pharmacokinetics of various opiates is outlined in Table 134.5. All opiates are weak bases and are moderately ionized at pH 7.4. Oral morphine is effective but undergoes hepatic first-pass metabolism, which is variable among patients. The oral dose for acute pain is two to five times the IV dose, whereas in long-term use the oral dose is 1.5 to 2.5 times the IV dose.

TABLE 134.5

Opiate Pharmacokinetics

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)
Morphine	2.2	3.3	15	30
Meperidine	3.2	2.8	5	58
Fentanyl	3.1	3.2	8	79
Sufentanil	2.7	1.7	13	92
Alfentanil	1.2	0.3	2.8	89

SS, steady state.

Modified from Baresh PG, Cullen BF, Stoelting RK et al., eds. Clinical Anesthesia. 2nd ed. Philadelphia: JB Lippincott; 1992.

Morphine is metabolized to morphine-3-glucuronide (M3G) and M6G in the liver. M3G is the major metabolite and has little morphine-like activity, although some research has suggested that M3G may be associated with an antinociceptive effect, accounting for failure of analgesia during long-term use.[29] In contrast, M6G is many times more potent than morphine itself.

Morphine undergoes significant first-pass hepatic metabolism, whereby after a single parenteral dose, only morphine is initially active. After a single dose by mouth (PO), both morphine and M6G are active. With long-term oral use, M6G accumulates until its analgesic effect is greater than that of morphine. A similar effect can be anticipated with long-term morphine infusion in the patient in the PICU. The kidney excretes the glucuronides, together with only a small amount of free morphine. Ninety percent of total urinary excretion occurs within 24 hours.

Tolerance, defined as an increase in the dose required to create the same response, is a potential problem with all opiates. Tolerance is mainly limited to the depressant actions of morphine, including analgesia, respiratory depression, anxiolysis, and drowsiness. Tolerance of morphine's inhibition of bowel motility and pupillary

constriction is minimal. The mechanism of tolerance appears to involve the degree and duration of both μ- and κ-receptor occupancy. It appears more rapidly after continuous infusion, and cross-tolerance to other opiates is common, although anecdotal evidence suggests that when opioids are switched, a dose reduction may be possible because cross-tolerance sometimes appears incomplete.[30] Receptor downregulation also may occur, as well as altered metabolism with an increased M3G/M6G ratio. Simultaneous blockade of *N*-methyl-D-aspartate receptors has been shown to be effective in reducing the development of tolerance.[31] Clinical tolerance appears uncommon with an exposure of less than 3 days, but after prolonged administration, doses 10 to 20 times that which would cause respiratory arrest in nontolerant patients may be tolerated.

Meperidine

Meperidine has one-tenth the potency of morphine. Compared with other common opioids, meperidine has more CNS excitatory effects including tremors, muscle spasm, myoclonus, psychiatric changes, and seizures. These effects may be due to a central serotoninergic effect.[32] It is metabolized by the liver to normeperidine, which is twice as toxic as meperidine and has a longer half-life (15 hours). Normeperidine accumulation is enhanced in patients with an induced cytochrome P-450 system. Meperidine has a shorter duration of action (2 to 3 hours) and has a more rapid onset because of its increased lipid solubility compared with morphine. Meperidine is unique among opioids because of its local anesthetic properties, which are capable of providing surgical spinal analgesia.[33] A small dose (0.125 to 0.25 mg/kg) of meperidine may be used to treat postoperative shivering.

Fentanyl

Fentanyl is one of the most commonly used opiates in the ICU. It is a synthetic derivative of meperidine without many of its unwanted side effects. It is a potent μ-agonist and is 100 times more potent than morphine. It has a rapid onset and cessation because of its high lipid solubility (Fig. 134.2). Fentanyl may be administered by several routes, including IV, intramuscular (IM), transmucosal,[34] and subcutaneous (SC) when venous access is inadequate. There is also a 12.5-mcg transdermal patch available for children. Fentanyl may be given intranasally as an alternative to the transmucosal route. It has been used for premedication, sedation, and also for the treatment of a "Tet" spell in an infant.[35] The transdermal patch is designed to release 12.5 mcg/h of fentanyl for approximately 3 days.[36] It is indicated for children with chronic pain syndromes; however, improved efficacy, compared to standard oral alternatives, has not been proved. Due to the different kinetics of fentanyl in children, it may take longer to achieve the steady state in the skin depot, and the patch may not last for a full 72 hours. The patch must be removed if the patient undergoes an MRI scan. Withdrawal from the fentanyl patch may be delayed due to the availability of the skin depot reserves. Unfortunately an increasing number of patients are now being admitted to the PICU[37] due to fentanyl overdose as a result of chewing, smoking, or extracting the fentanyl from the patch. A 12.5-mcg fentanyl patch contains over 1 mg total of fentanyl.

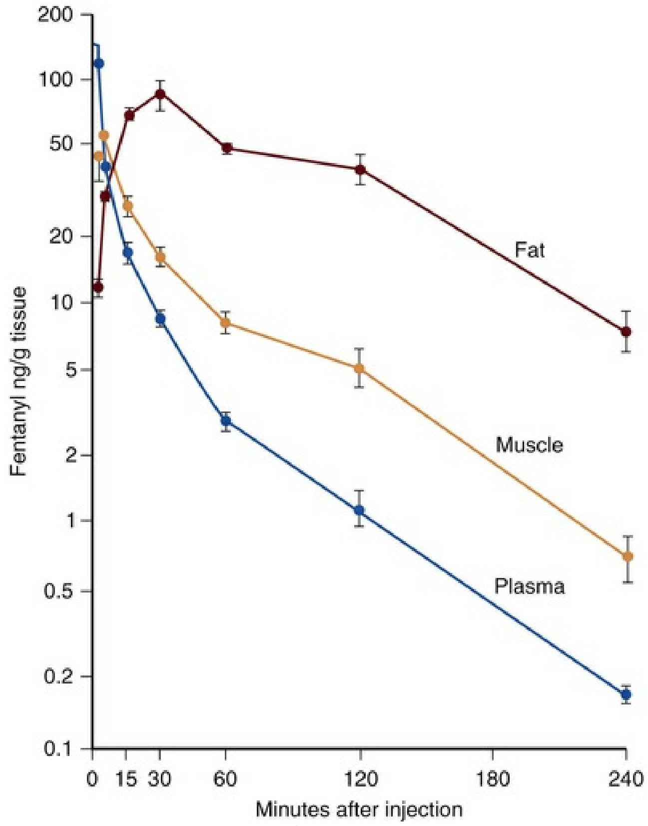

FIG. 134.2 Initial fentanyl redistribution.

Skeletal muscle rigidity (which can occur with all synthetic opiates) is well described in the literature. It is mediated through the CNS and is an idiopathic response usually associated with a large bolus dose (≥5 μg/kg). It improves with the administration of NMBAs and is reversible with naloxone. Fentanyl has limited cardiovascular effects. Moderate bradycardia is the most common hemodynamic effect. Fentanyl does not cause histamine release. Dosing in the ICU is either by bolus (1 to 2 μg/kg) or infusion (1 to 4 μg/kg/h with higher doses as tolerance develops). The short duration of effect of a single dose of fentanyl is not due to metabolism but rather to rapid redistribution. Maximum brain concentration after a bolus is achieved within 90 seconds. Then, because of rapid redistribution, the plasma level falls by 50% in 30 minutes, and the result is a clinical duration of effect of a single dose of approximately 30 minutes. Fentanyl then accumulates in fat, where it is stored and slowly released with a longer elimination half-life of about 4 hours (longer than morphine). Marked respiratory depression occurs within 120 seconds, and a single dose of 5 μg/kg will cause apnea in 50% of patients. Also, fentanyl is metabolized by the liver to norfentanyl and hydroxy fentanyl derivatives, both of which are thought to be inactive. In the operating room, high-dose fentanyl is commonly used for cardiac anesthesia and for anesthetization of other unstable patients. A loading dose of 50 μg/kg, followed by 0.5 μg/kg/min, will occupy all opioid receptors and produce a state of anesthesia. Many cases of awareness with patients under anesthesia have been documented, however, even when these high doses of fentanyl were used.

Sufentanil

Sufentanil is another synthetic opiate that has actions and therapeutic effects that are similar to those of fentanyl. It is five to ten times more potent than fentanyl and is the most potent opioid in clinical practice, posing a high risk of apnea with bolus administration. Dosing recommendations include bolus dosing of 0.2 to 0.4 μg/kg or an infusion of 0.2 to 1 μg/kg/h.

After a single bolus, sufentanil has kinetics similar to that of fentanyl with a short duration of clinical effect of approximately 30 minutes. However, with prolonged use, sufentanil accumulates less and is associated with a more rapid recovery after infusion because of its smaller volume of distribution and similar clearance. When the patient is receiving high doses of fentanyl, sufentanil is useful to conserve infusion volume.

Alfentanil

Alfentanil is another synthetic opiate with a rapid onset. It is five times less potent than fentanyl. Although it is less lipid soluble than fentanyl because of its low pK_a (negative logarithm of the acid ionization constant), a higher percentage of the drug is present in the active unionized form, which results in a rapid onset. Because of its low volume of distribution, alfentanil has a short elimination half-life, which results in a short duration of action (5 to 10 minutes). Dosing regimens include boluses of 5 to 10 μg/kg if there is spontaneous respiration or 20 to 50 μg/kg if the patient's lungs are ventilated. Alfentanil is a useful agent for preventing the hypertensive or increased intracranial pressure (ICP) response to intubation. As with all synthetic opiates, there is a risk of muscle rigidity with the higher dosing. Infusion dosing is typically 0.2 to 1 μg/kg/min for patients receiving mechanical ventilation. Postinfusion recovery is quicker with alfentanil than with fentanyl. It is useful by infusion and safe to use in patients with hepatic or renal failure.

Codeine

Codeine has a chemical structure and effects that are similar to those of morphine; it is commonly used as an oral medication for cough suppression or mild to moderate pain relief. A large part of its effects are due to the metabolism of codeine to morphine. Ten to twenty percent of patients lack a metabolic pathway to convert codeine to morphine, which results in an unpredictable effect. Dosing is 0.5 to 1 mg/kg. Constipation is a major adverse effect, and some patients report having a vague, peculiar, or unpleasant feeling when they take codeine. This drug can be habit forming. It can be given orally, IM, or rectally. Rapid IV use may result in cardiovascular collapse. Rectally administered codeine has been shown to have as rapid an onset as IM codeine, but it yields lower peak levels in children.[38] Codeine has been the analgesic of choice by neurosurgeons because of the belief that pupillary signs are maintained with use of this drug. Morphine has been shown to be a more effective analgesic, however, in patients with head injuries.[39]

Remifentanil

Remifentanil is one of the newest synthetic opiates available. It was designed to be metabolized by plasma esterases to provide a short half-life. It is a potent μ-agonist

with mild κ and δ effects. It is substantially more potent than fentanyl. It is supplied as a white lyophilized powder that contains glycine and should not be used for epidural or spinal analgesia. The metabolism is by nonspecific esterases not affected by pseudocholinesterase deficiency. The metabolite, a weak μ-agonist, is excreted by the kidney. The kinetics of remifentanil is different from those of most opiates used in the ICU. It has a short half-life that is due to metabolism rather than to redistribution. Therefore remifentanil has what is known as a context-sensitive half-life. The elimination half-life for remifentanil is about 8 minutes. With an infusion of remifentanil, the half-life does not increase but remains constant. With opiates such as fentanyl and alfentanil (Fig. 134.3), the clinical effect half-life increases with time until it reflects the elimination half-life of between 2 and 4 hours.

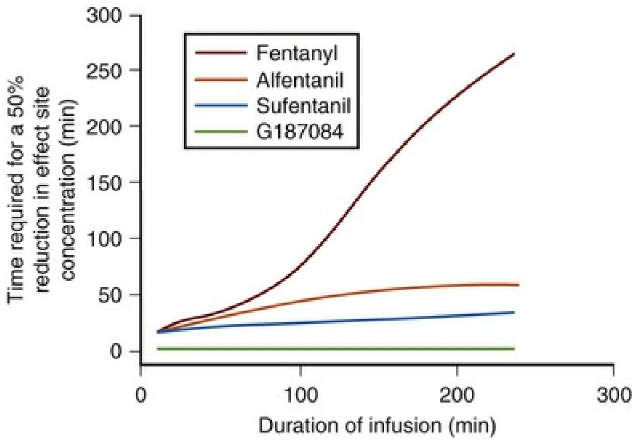

FIG. 134.3 Context-sensitive half-life.

The kinetics reported for neonates is similar to those reported for adults. The continuous infusion rate depends on the degree of sedation/analgesia required (0.1 to 0.5 μg/kg/min for sedation; 0.75 to 2 μg/kg/min for balanced anesthesia; 4 μg/kg/min for loss of consciousness). Remifentanil has effects on the cardiovascular system that are similar to those of fentanyl. Remifentanil causes a mild bradycardia and a slight decrease in blood pressure,[40] which may be prevented with glycopyrrolate. No histamine release occurs. Remifentanil is a potent respiratory depressant. For spontaneous respiration, a low continuous infusion dose (without a bolus) should be used (0.1 μg/kg/min). Sedation can be effectively managed by continuous infusion without the need for a bolus because of the short half-life. An increase or decrease of infusion rate is rapidly reflected by a change in the degree of sedation, which is important to note. Most other opiate sedatives require bolus dosing to achieve a rapid change in effect. This type of dosing is neither appropriate nor needed for remifentanil.

Remifentanil has the usual opiate adverse effects; however, because of the short half-life, these clinical effects are brief. Remifentanil may prove to be a safe and effective choice for PICU sedation in patients with severe renal or hepatic disease; however, the potential exists for glycine accumulation in patients with renal failure. It is an option for those who require overnight ventilation or for those patients in whom a rapid awakening may be required for neurologic assessment. Remifentanil has been shown to reduce cerebral oxygen use and reduce cerebral blood flow if the

CO_2 is maintained in a normal range. Remifentanil is currently an expensive option and should not be considered for every patient. Also, because of its short duration, the postoperative patient may need an alternative analgesic after extubation. Rapid development of opiate tolerance with remifentanil has been described in healthy volunteers[41] and also when used in the ICU setting. This rapid tolerance has also been described in postoperative scoliosis patients[42]; however, the increased morphine requirements described probably reflect the initial postoperative need to achieve an adequate morphine blood level rather than any acute tolerance.

Hydromorphone

Hydromorphone is a hydrogenated ketone of morphine. It is seven times as potent as morphine with a similar onset and duration of action. It causes less histamine release than morphine and may be used in patients who report pruritus due to morphine. Like morphine, hydromorphone undergoes hepatic metabolism; however, no active metabolites are dependent on renal excretion. As such, it may be an effective alternative in patients with renal insufficiency or failure.

Tramadol

Tramadol is an opiate analgesic. It action is due to the metabolite O-desmethyltramadol, which relieves pain by binding to opiate receptors and by inhibiting the reuptake in the CNS and spinal cord of norepinephrine and serotonin, two pain-modifying neurotransmitters. Tramadol does not have antiinflammatory effects. Its use is indicated in cases of moderate to severe pain.[43] Even though it is a narcotic-like agent, the Food and Drug Administration (FDA) only recently classified tramadol as a controlled substance. Tramadol has been changed to a schedule IV medication, reflecting issues and concerns about tolerance, habituation, abuse potential, and withdrawal syndrome.[44] Dosage (not FDA approved for patients younger than 16 years) is an initial oral administration of 1 to 2 mg/kg every 6 hours and should not exceed 6 mg/kg/day. An IV preparation is available outside of the United States. Patients with a creatinine clearance less than 30 mL/min should not receive more than one dose every 12 hours, with a maximum dose of 3 mg/kg/day. The dose for patients with cirrhosis or hepatic dysfunction is 1 mg/kg every 12 hours. Patients undergoing dialysis can receive their dose on the day of dialysis because only 7% of the drug is removed by the process. The adverse effects of tramadol most often involve the CNS and the GI tract. Patients may become dependent on tramadol. Abuse is possible, and it should not be given to opiate-dependent patients. Seizures have been seen in patients receiving high single oral doses of 10 mg/kg; this danger is even greater in patients with epilepsy and in anyone taking monoamine oxidase inhibitors and neuroleptic agents that lower the seizure threshold. Respiratory depression may occur if the recommended dosage is consistently exceeded or if another centrally acting depressant drug (eg, alcohol) or an anesthetic is given concurrently. Because of the possibility of withdrawal symptoms, patients should not abruptly discontinue use of tramadol. Tramadol is not a useful drug for sedative action.

Table 134.6 provides conversion doses for some commonly used oral opiates. A summary of IV doses of different opiates is provided in Table 134.7.

TABLE 134.6

Dose Equivalents: Short Acting

Drug	Oral	Parenteral
Morphine	0.5 mg/kg q4h	0.15 mg/kg q3h
Hydromorphone	0.1 mg/kg q4h	0.02 mg/kg q4h
Codeine	4 mg/kg q3h	
Hydrocodone	0.5 mg/kg q3h	
Oxycodone	0.5 mg/kg q3h	
Meperidine	5 μg/kg q2h	1.5 mg/kg q2h
Fentanyl		1.5 μg/kg q2h

TABLE 134.7

Summary of Opiate Dosing

Drug	Relative Potency	Bolus Dose	Initial Infusion Rate	Active Metabolites
Morphine	1	0.1 mg/kg	0.04 mg/kg/h	M6G
Meperidine	0.1	1 mg/kg	NA	Normeperidine
Fentanyl	100	1 μg/kg	1 μg/kg/h	None
Hydromorphone	7	0.015 mg/kg	0.005 mg/kg/h	None
Sufentanil	500	0.2 μg/kg	0.2 μg/kg/h	None
Remifentanil	NA	NA	0.1 μg/kg/min	None
Alfentanil	10	10 μg/kg	10 μg/kg/h	None
Methadone	1	0.1 mg/kg	NA	None

M6G, morphine-6-glucuronide; *NA*, not applicable.

Opiate Antagonists

Several opiate antagonists are available. The most commonly used is naloxone, which is a specific and sensitive receptor antagonist of all opiate receptors. It is administered in either low doses (1 μg/kg) or high doses in an emergency situation (10 μg/kg). If the drug cannot be administered intravenously, then it can be given intramuscularly, intranasally, or into the midventral surface of the tongue. When naloxone is being used for a long-acting agonist, an infusion may be necessary because its half-life is only 30 to 81 minutes (mean of 64 ± 12 minutes). In neonates, the half-life has been reported as 3.1 ± 0.5 hours; however, this prolonged effect is likely to be offset by a concomitant increase in the duration of action of the opioid for which the naloxone is given. No effect is seen in the healthy patient in the absence of administered opioids; however, in the setting of sepsis in the ICU, a vasopressor effect may occur, presumably because of an interaction with endogenous opioids released in response to stress. Nalmefene, a longer-acting antagonist, can be given through IV, IM, and SC routes. It has a redistribution half-life of 41 minutes and a terminal half-life of 10.8 hours in adults and somewhat less in children. Thus reappearance of the antagonized opioid is unlikely if it is given in an adequate dose.[45]

There has been a growing interest in the use of opiate antagonists in the management of opiate sedation induced ileus. Naloxone can be given orally[46]; however, there is evidence of a central effect that slightly reduces the efficacy of parenterally administered opiates. Two opiate antagonists are available that have been approved for opiate-induced constipation. Naloxegel[47] is a PEGylated naloxone that does not cross the blood-brain barrier, inhibits opioid receptors in the

gastrointestinal tract, and improves gastrointestinal motility. Methyl naltrexone is also approved for opiate-induced constipation. These drugs are not routinely used; however, they may be added to bowel regimes to prevent opiate-induced bowel dysfunction.

Incidental Pain Syndromes in the Pediatric Intensive Care Unit

Although the techniques used to sedate children are often applied in order to facilitate their PICU management, many children have pain that is related to their underlying condition. Many options are available for controlling pain in the pediatric patient (Box 134.1). The pharmacologic management of pain should follow the traditional World Health Organization analgesic ladder, which begins with a nonopioid analgesic such as a nonsteroidal antiinflammatory drug or acetaminophen, followed by a weak opioid such as hydrocodone added to the nonopioid, and then a strong opioid such as morphine or hydromorphone as needed. When taken orally, a sustained-release preparation is often useful once the dose requirement has been determined. The dose requirement of a strong opioid is variable in the patient taking opioids for a prolonged period, and not appreciating this variability is a common cause for therapeutic failure. In addition, once a dose requirement is known, the analgesic should be given to preempt pain rather than to relieve pain as required. At each level of analgesic use, the addition of adjuvant medications should be considered. Adjuvant drugs fall into six groups: antidepressant, anticonvulsant, neuroleptic, steroid, stimulant, and local anesthetic. Of the tricyclic antidepressants, nortriptyline is available in a liquid form. The tricyclic antidepressants are indicated for neuropathic pain, particularly when the patient describes a burning pain. Also useful for neuropathic pain are the anticonvulsant agents gabapentin, pregabalin, and carbamazepine. These drugs often work best when the pain is described as shooting or lancinating. Neuropathic pain may result from tumor invasion, vincristine therapy, cytomegalovirus infection, or human immunodeficiency infection. Neuroleptic drugs, including chlorpromazine and trimeprazine, may be useful in the management of nausea, anxiety, and pruritus. Steroids benefit mood, inflammation, nausea, appetite, nerve swelling/entrapment, and vasculitis. When opioid sedation is interfering with quality of life, a stimulant such as an amphetamine may restore energy and alertness while allowing ongoing analgesia from the opioid. Sometimes pain can be managed by local anesthetic, placed by peripheral nerve block, topically, or as a neuraxial block.

Patient-controlled analgesia (PCA) has become the mainstay of postoperative pain relief in children because of its efficacy and safety. However, its use is limited by the child's ability to understand how to use the PCA pump. Proxy PCA (PCA-P) has been used for younger children or those with cognitive impairment.[48] The use of the PCA by the nurse or the caregiver may override the safety net that the PCA has. The use of PCA-P has been associated with greater need for rescue interventions; however, it is often used in sicker children. When PCA-P is used, careful evaluation and rigorous monitoring are needed.

Sickle Cell Crisis

Sickle cell disease differs from cancer and acquired immune deficiency syndrome in that intermittent episodes of severe pain occur, requiring urgent intensive treatment. A good review of this subject has been published.[49] Chronic pain also may be present because of long-term tissue and bone damage from periods of ischemia during past crises, including persisting myocardial ischemia. Patients may be receiving long-acting opioids or may have had repeated exposure to opioids with past crises. Patients with a sickle cell disease crisis that involves the chest or brain are likely to be admitted to the PICU. Chest crises result from the sickling of erythrocytes in the pulmonary vasculature and result in hypoxia to the rest of the body and local lung damage. The systemic hypoxia worsens the crisis and is thus self-perpetuating. Chest radiograph changes may be late, and an associated paralytic ileus may be present.

Poor pulmonary function may discourage the practitioner from using adequate opioid analgesics out of concern for worsening the hypoxia. However, it is important not to underestimate the need for pain relief and to appreciate that past opioid exposure may have resulted in tolerance to opioids. It is important that the pain is assessed early and quickly treated. Also the pain must be reevaluated to ensure that additional doses are given in a timely manner.[50] If considering the use of a PCA, then appropriately dosing must be considered as well. These patients are often not opiate naive, and if the PCA is inadequately dosed then the patients will not achieve a satisfactory level of analgesia. These patients also require frequent pain reevaluation by the nurse to ensure that the PCA is programmed appropriately. If IV access is difficult to obtain, morphine may be given subcutaneously or orally. Ketamine has been suggested as an adjunct to sickle cell pain crisis,[51] demonstrating in a small review an improvement in pain scores as well as a reduction in opiate requirements. Anecdotal success also has been reported with nebulized morphine.[52]

Opiate Tolerance

The use of opiate infusions in the ICU is associated with the potential for the development of tolerance or dependence.[53] Iatrogenic withdrawal symptoms can occur if the opiates are discontinued abruptly. These effects have been shown to be related to the total dose and duration of fentanyl infusion. A fentanyl infusion of 5 days or a total cumulative dose of 1.6 mg/kg during the hospital stay was associated with a 50% chance of the development of narcotic withdrawal, whereas a fentanyl infusion of 9 days or longer or a total cumulative fentanyl dose of 2.5 mg/kg or more during the hospital stay had a 100% incidence of withdrawal.[54] The rising plasma fentanyl levels caused by increased dosing suggested that increased metabolism or clearance was not responsible for the development of tolerance. A study of patients in a PICU conducted to determine the degree of opiate tolerance showed a significant increase in opiate dosing required for adequate sedation.[55] The opiate infusion increased by about 80% per week for the first 3 weeks of opiate use. No difference in the rate of opiate increase was found with respect to age of the patient, postoperative status, mode of ventilation, and paralysis.

For patients considered to be at risk of withdrawal, several options are available. If circumstances allow, it is better to start the treatment for withdrawal prevention before the patient has symptoms and signs of withdrawal. Opiate withdrawal is not usually a serious medical problem; it is rarely life threatening and is self-limited.

However, treatment should begin early if possible for patient comfort. In a few circumstances the associated hypersympathetic state may not be good for the patient. The signs and symptoms of withdrawal are nonspecific, and other causes, such as infection, hypoglycemia, hypocalcemia, hyperthyroidism, and hypoxia, should be excluded. Because of the nonspecific nature of the symptoms of opiate withdrawal, several scoring systems have been described to aid with the diagnostic process. The Finnegan score is based on 31 variables and is lengthy. The Lipsitz score is shorter and easier to use than the Finnegan score. Both of these scoring systems, however, were devised for use with neonates, and several of the measurements are not appropriate for patients in the PICU. Currently no validated scoring system exists for assessing opiate withdrawal in the pediatric patient. In the limited number of articles in which opiate withdrawal in the PICU is evaluated, the authors have modified these scores (Table 134.8) in an attempt to provide an objective assessment of the patient.

TABLE 134.8

Signs and Symptoms of Opiate Withdrawal

Sign/Symptom	Examples
Neurologic excitability	Sleep disturbances
	Agitation
	Tremors
	Seizures
	Choreoathetoid movements
Gastrointestinal disturbances	Vomiting
	Diarrhea
	Autonomic dysfunction
Hypertension (>150 mm Hg)	Tachycardia (>150 mm Hg)
	Tachypnea (>40 beats/min)
	Fever (>38.58°C)
	Frequent yawning
	Sweating
	Goose flesh
	Mottling

The assessment of a new score based on a similar set of signs and symptoms, the Withdrawal Assessment Tool,[56] has been proposed. The bedside nurse reviews the patient's chart for the previous 12 hours and performs a short assessment of the child's level of agitation as well as other signs/symptoms. This review is then followed by an assessment of the response to stimulus and also how quickly the child settles down after the stimulus. A score of 1 is assigned to each assessment (maximum, 12). A score of greater than 3 was associated with a greater likelihood of drug withdrawal. Although this score is new and has limited verification, it probably provides a better evaluation than the clinician's bedside opinion, especially in complex cases in which both opiate and BZD withdrawal may occur together.

Several therapeutic options are available for the prevention and treatment of opiate withdrawal. Drugs from the same class are preferable. The FDA has approved methadone for opiate withdrawal. Other agents that may be useful include morphine, clonidine, dexmedetomidine, phenobarbital, paregoric, chlorpromazine, the transdermal clonidine patch,[57] and SC fentanyl. Paregoric contains morphine plus papaverine, noscapine, camphor (a CNS stimulant), ethanol (45%), benzoic acid (which competes with bilirubin-binding sites), and glycerin (which causes diarrhea). Paregoric has been used for neonatal withdrawal, but because of its composition, it

may cause adverse effects. Chlorpromazine may be useful for GI adverse effects, but hypothermia and hypotension may occur. Haloperidol also may be of use, having minimal respiratory depression and no active metabolites. It also offers cardiovascular stability. Phenobarbital has been used for hyperactive behavior; however, it can cause significant CNS depression, it induces drug metabolism, and it is tolerance/dependence forming.

Methadone seems to be the most suitable agent for treating opiate withdrawal. It has an oral bioavailability of 80% to 90% and an elimination half-life of 12 to 24 hours. It is equipotent to morphine. Methadone has inactive metabolites and is less sedating than morphine while remaining an effective analgesic. Because of its higher bioavailability and reduced first-pass metabolism, the effect of oral doses is more predictable than that of morphine. Methadone has been extensively used in the outpatient management of patients addicted to opiates.

The convenience of the oral route, the less-frequent dosing because of its longer half-life, and the ease of calculating doses because of its equal potency to morphine make methadone attractive for use in the management of opiate withdrawal in children. However, a huge variability exists in recommendations regarding the methadone dose that should be used to prevent opiate withdrawal in children. Several factors are important in the dosing of methadone for withdrawal from fentanyl. After prolonged IV administration, fentanyl has a potency 100 times that of methadone; it has a metabolic half-life approximately one-quarter that of methadone; and if given intravenously, it has a bioavailability 20% greater than orally administered methadone. In a study in which the effectiveness of a fentanyl-methadone conversion protocol was assessed, researchers found that giving 2.4 times the daily fentanyl dose as methadone prevented withdrawal symptoms.[53] Methadone was given intravenously for 24 hours, and the fentanyl dose decreased by 50% on day 1 and by another 50% on day 2, and then it was discontinued. On day 3, the methadone was converted to oral dosing. The methadone was given intravenously initially. Because of its long half-life, oral dosing could take up to 5 days to reach a steady state. The duration of methadone requirement varied from 1 to 4 weeks, depending on the duration of opiate infusion. Methadone was being weaned by 3% to 15% per day with no signs of withdrawal. To date, there have been no published cases of respiratory arrest when methadone has been used for opiate weaning.

The incidence, risk factors, and best management strategy for opiate withdrawal in the PICU are still open to debate. Several articles have suggested that there are many risk factors for withdrawal. Younger age, higher level of critically illness, duration, and cumulative dose may be important patient variables,[58] but not all studies demonstrate these same risk factors. Postoperative patients appear to be less likely to develop tolerance, as are postoperative patients who received morphine rather than fentanyl; however, in nonsurgical patients the opiate chosen was not significant.[59] Of those patients receiving opiates for more than 4 days, 35% required the dose to be doubled by 14 days. Most of these increased dose requirements occurred with 3 to 6 days. Starting at a lower dose was also a risk factor for increased dose requirements. In this study, however, the opiate doses used were very low, with a peak fentanyl dose of only 4 mcg/kg/h, so these factors may not apply in patients receiving higher doses. Of interest, the concomitant use of midazolam infusions also was associated with increased opiate needs; whether this reflects a

patient factor or a drug effect is unknown. As with most studies and also in clinical practice, these patients received a multitude of sedative-analgesic agents, which can confuse the picture. This study was completed at seven tertiary PICUs, and when the opiate dosing and trends were compared, there was a significant difference between the institutions. This reflects the great variability in sedation requirements among patients, clinicians, and institutions, and as such care should be taken when interpreting these results and instigating changes in a PICU based solely on published data. Part of this variability is patient specific, but there are also ICU- and hospital-dependent factors that can influence the development of tolerance and withdrawal.[58] There is some belief, but little evidence, that using sedation protocols can reduce this problem. Intermittent rather than continuous infusions can reduce the risk; however, this option has to be balanced against the primary aim of sedation, which is patient comfort and safety; with changing levels of sedation, especially in younger children, this could pose a problem. Weaning protocols and the use of methadone have been shown to reduce the incidence of withdrawal; however, various management strategies have been utilized with varying results.

Finally, hospital-based factors can play a part. It would appear prudent to initiate the conversion from fentanyl/morphine to methadone in the ICU environment in the event that problems arise and to ensure that an adequate dose is given. Once stabilized, the patient may be transferred to the floor and ultimately home, with a clearly described plan for decreasing the methadone dose over time. The weaning plan also should involve the home pediatrician so that patients have access to someone who is familiar with the process. In a follow-up of patients who had received methadone while in the ICU, 38% of patients were discharged home during the weaning process. No problems were associated with the weaning of methadone at home. Stigma regarding methadone use was not expressed by any of the parents.

Bed availability in the ICU can influence this factor. Also, most floors will not allow the use of ICU sedation infusions, so they must be converted to alternatives prior to transfer. Continuing the patient on an opiate infusion wean can increase the ICU length of stay substantially.

An alterative to fentanyl equivalence-based methadone dosing has also been reported.[60] In this study, the patients received either a fixed low dose (0.1 mg/kg) of methadone or a high dose (fentanyl dose (mcg/kg/h) × 0.1 × weight) of methadone, irrespective of the dose of fentanyl. The methadone was tapered in a fixed manner irrespective of the duration of fentanyl infusion. There was no difference in the success (about 60%) of the methadone taper between the doses. However, four times as many patients in the high-dose methadone group became oversedated. The success rate of either of these protocols appears to be poor, possibly due to the fairly rapid wean of the methadone, irrespective of the duration of opiate exposure. Also of note, the peak fentanyl dosing was low (4 mcg/kg/h) and the cumulative dose was also low (0.59 mg/kg), both below what are considered high-risk factors. This is an important consideration because if using the high-dose strategy, the methadone dose based on a much higher fentanyl rate would expose the patient to very high doses of methadone and risk respiratory depression. Also, methadone accumulates over several days, and this respiratory depression could occur when the child is not being monitored as closely, after transfer to the floor.

This study supports the use of the lowest dose possible to prevent withdrawal. If the dose is too low, then small (25%) adjunct doses of methadone can be given to

control the withdrawal symptoms and then, if needed, the methadone dose can be modified to reflect the patient's actual requirements. Titration to effect is no different from our standard of practice for sedation and analgesia. In younger children, a Q8- or 12-hour dosing schedule may mean that the doses are being administered too far apart and occasionally a Q6-hour schedule may be required in the initial few days; again caution must be observed with respect to drug accumulation during this period. The purpose of the methadone is to prevent withdrawal symptoms and keep the child comfortable. This should be achieved with the smallest dose possible, which is safer and allows for a shorter methadone taper period. The dose of methadone to prevent withdrawal in most circumstances will be lower than that required to cause sedation. Patient safety is paramount; opiate withdrawal, although unpleasant, is not dangerous and with appropriate assessment and timely intervention can be corrected quickly; excess sedation should be avoided.

The use of a clonidine patch also has been evaluated in the PICU. Clonidine has been shown to be effective in the management of nicotine, opiate, and alcohol withdrawal. It decreases sympathetic outflow from the CNS and has a synergistic effect for analgesia, both at the central and spinal level. In one report, eight patients were described after tracheal reconstructive operations. They required postoperative sedation and ventilation for 7 days, which put them at high risk for withdrawal.[24] A clonidine patch was applied 12 hours before extubation, and the patients were weaned off the opiate. The dose used was approximately 6 μg/kg/day of clonidine, and the patch was left on for 7 days. One patch had to be removed because of hypotension. The patch seemed to be effective in preventing withdrawal. Use of the clonidine patch is attractive because of its noninvasive approach, which is desired. However, the use of a transdermal patch prevents titration of the effect, and problems with bradycardia, hypotension, hypothermia, sedation, and dysrhythmia may occur.

A confounding issue in many publications and in the clinical management of opiate withdrawal is the potential for simultaneous BZD withdrawal. Most researchers have not been able to separate these two issues. The symptoms of BZD withdrawal differ from those of opiate withdrawal because the BZD symptoms generally include less sympathetic activation. BZD withdrawal symptoms are characterized by agitation and a movement disorder. If BZD withdrawal is a concern, low-dose lorazepam or diazepam may be added to the withdrawal management strategy (Table 134.9). A prospective study of BZD withdrawal[61] following lorazepam infusion (up to 0.3 mg/kg/h) documented BZD withdrawal syndrome in approximately 25% of the children. This withdrawal occurred even when using a 6-day tapering of the lorazepam dose. All of the children had been previously weaned off fentanyl infusions. No predisposing risk factors were found for BZD withdrawal with respect to BZD or opiate dosing or duration.

TABLE 134.9

Pharmacokinetics of Benzodiazepines

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)
Diazepam	46.6	1.13	0.4	97.8
Midazolam	3	1.09	7.5	94
Lorazepam	14.5	1.1	1.1	91
Flumazenil	0.67	1.2	15.3	50

SS, steady state.

Rapid Opiate Detoxification

Reports have been made of rapid opiate detoxification in the ICU. These procedures have used a form of deep sedation (often with use of propofol or another anesthetic agent) to facilitate opioid withdrawal in patients addicted to the recreational use of opiates.[62] The patients are given high doses of opiate antagonists to displace all opiates from the receptors, and then heavy sedation is initiated to reduce the occurrence and effects of the sympathetic stimulation observed with short-term opiate withdrawal. These procedures have been safely performed in the ICU; however, there have been several reports of complications[63] when these procedures were not performed with full ICU support. Currently the effectiveness and safety of 1-day opiate detoxification are still under debate.[64] If used, however, it should be combined with an established long-term support plan to optimize long-term success.

In the PICU, deep sedation with propofol has been used to facilitate rapid opiate weaning of ventilator-dependent patients.[65] The use of propofol for up to 3 days allowed a reduction of fentanyl dosing from 24 to 9 μg/kg/h (a 65% reduction). No signs or symptoms of opiate withdrawal were noted, and metabolic acidosis did not develop. Opiate antagonists were not used for this rapid weaning process. However, concern has been raised regarding the long-term administration of propofol, especially in the PICU patient, given the development of the propofol infusion syndrome.

Benzodiazepines

Benzodiazepines (BZDs) are among the most commonly used agents for sedation in the ICU. They augment the function of the GABA type A ($GABA_A$) receptor at the postsynaptic membrane. This pentameric protein controls a chloride channel, the opening of which leads to an inhibitory effect due to hyperpolarization of the cell membrane.[66,67] Benzodiazepines bind to BZD receptors, which in the CNS are usually found as part of the $GABA_A$ receptor, enhancing the effect of endogenous GABA.[68] Peripheral BZD receptors[69] are not usually associated with the $GABA_A$ receptor but are a binding site for diazepam and midazolam. These 18-kDa proteins are associated with regulation of cellular proliferation, immunomodulation, porphyrin transport, heme biosynthesis, and anion transport. In particular, they seem important in the regulation of steroid synthesis and apoptosis, and they have a significant effect on the hypothalamic-pituitary-adrenal axis.[70] These latter effects may be pertinent to the physiologic care of patients in the ICU.

BZD receptors are bound by a family of endogenous peptides called endozepines, which have similar effects to the BZDs.[71,72] The expression of this diazepam-binding inhibitor may be relevant to the development of dependence not only on BZDs but also on alcohol and opioids[73] and may therefore be relevant in the drug dependence commonly seen in patients in the PICU who are given these agents continuously. Naturally occurring BZDs have been detected with structures similar to those used clinically.[74] Subsets of $GABA_A$ receptors have been shown to have different effects. Type 1 receptors were responsible for sedation and anterograde amnesia, whereas

type 2 receptors mediated anxiolysis. It may be possible to develop selective subtype receptor agonists to provide anxiolysis without sedation, amnesia, or dependence.

The general pharmacologic effects of BZDs are sedation, anxiolysis, euphoria (limbic system), reduced skeletal muscle tone (through spinal BZD receptors), anticonvulsant properties, and neuroendocrine effects. They impair acquisition and encoding of new information, providing anterograde amnesia. They do not have any analgesic properties. They have little direct effect on ICP. Their effects are dose dependent. Patient cofactors including age, concurrent disease, and any cosedation therapy influence responses to BZDs. Paradoxical reactions are reported in which agitation rather than calming is observed.[75] In healthy patients, BZDs have few cardiovascular adverse effects, but in a sick, intensive care population, profound cardiovascular depression may be observed occasionally. BZDs should be used judiciously until the patient response is known.[76] Midazolam has been most often associated with this effect,[77] and research in dogs has shown both negative inotropy and chronotropy, especially when the sympathetic response has been abolished.[78] Clinical use is largely encompassed by discussion of the pharmacologic properties of diazepam, midazolam, and lorazepam.

Specific Benzodiazepines

Diazepam

The first widely used BZD in the ICU was diazepam. Because of its low solubility in water, it is available in the IV or IM form dissolved in propylene glycol. This formulation causes a significant amount of pain and thrombophlebitis with peripheral IV use. A lipid emulsion that has fewer adverse effects is available in the United Kingdom. Diazepam is inexpensive and is effective for short-term sedation; in such cases, accumulation is less of a concern. Diazepam may be given orally because it has good absorption, but absorption tends to be erratic when it is given rectally or intramuscularly. It is highly lipid soluble with a long half-life (24 hours). Metabolism by oxidative biotransformation generates several hypnotically active metabolites with an elimination half-life that may be longer than diazepam, including oxazepam (half-life, 10 hours) and N-dimethyldiazepam (half-life, 93 hours). Delayed recovery has been reported in neonates after they received diazepam, possibly because of the long half-life of dimethyldiazepam.[79] Prolongation of effects occurs in patients when clearance is reduced because of hepatic dysfunction and when metabolism is inhibited by drugs such as cimetidine and omeprazole.

Midazolam

Midazolam is an imidazobenzodiazepine. It has a short elimination half-life of 2 hours and is water soluble, which means that IV injection is nonirritating. Because of these factors, it has become popular in ICUs for sedation by infusion. Intranasally (0.2 mg/kg), midazolam has proved to be as effective at controlling febrile seizures as IV diazepam (0.3 mg/kg).[80] Intramuscular midazolam can be as safe and effective as IV lorazepam in managing patients with status epilepticus.[81] Midazolam has extensive first-pass metabolism and provides less reliable results when given PO,

although this route is often successfully used for premedication of children before general anesthesia in doses of 0.5 to 0.75 mg/kg (maximum, 20 mg). It is available in a pleasant-tasting cherry syrup and is effective in 10 to 15 minutes, providing up to 1 hour of adequate anxiolysis, although residual hangover effects may persist.[82] Rectal and sublingual administration have been described.

Midazolam is about eight times more potent than diazepam, with starting dose recommendations of a bolus dose of 0.05 to 0.1 mg/kg[83] and an infusion of 1 to 6 μg/kg/min. Midazolam is metabolized by the cytochrome P-450 system subfamily IIIA (nifedipine oxidase), polypeptide 4 (CYP3A4),[84] to hydroxymidazolam (63% potency) and hydroxymidazolam glucuronide (9% potency). Because of the high degree of protein binding (94% protein bound), the free level can be significantly changed with interactions because of the protein binding, which also may occur with heparin. Hepatic or renal failure increases the free fraction by two to three times, and its effect also can be prolonged by the accumulation of active metabolites.[85] The half-life of midazolam in patients in the ICU may be prolonged compared with that in healthy patients.[86] With short-term infusions (<12 hours), it retains a rapid recovery; however, with increased duration of use, the recovery becomes prolonged. Its clearance may be reduced by several commonly used ICU drugs, including calcium channel blockers, erythromycin, and triazole antifungal agents.[87]

Midazolam clearance can also be reduced by mechanical ventilation, possibly due to reduced cardiac output.[88] There appears to be no correlation between day-night cycle and midazolam pharmacokinetics in critically ill children. Critical illness itself can have a major effect on midazolam clearance. Using pharmacokinetics modeling it was found that midazolam clearance is lower in critically ill patients when compared to healthy infants admitted for postoperative monitoring; this is believed to be due to reduced cytochrome P-450 3A4/5 (CYP3A4/5) activity as a result of inflammation, reduction in liver blood flow as a result of mechanical ventilation or acute illness, and the reduction of total albumin that is usually reported in critically ill patients.[81]

Lorazepam

Lorazepam is an alternative water-soluble agent that is well absorbed after both oral and IM administration.[89] It produces sedation for 4 to 8 hours after a single dose. Lorazepam has a slower onset than does midazolam. The elimination half-life is about 14 hours. Metabolism is by glucuronyl transferase, not the cytochrome P-450, and there are no active metabolites. This metabolism is unaffected by cimetidine or phenobarbital, which only affects oxidative metabolic pathways. Sodium valproate may inhibit its metabolism.[90] In persons with advanced liver disease, these phase II glucuronidation reactions are better preserved, and the increased half-life seen is due to increases in the volume of distribution rather than to reduced clearance. In patients with renal failure, prolonged half-life is also due to reduced protein binding because clearance is unchanged. No change in metabolism occurs with aging or critical illness. In a comparison of infusions of midazolam and lorazepam, the recovery characteristics were found to be significantly different. In patients receiving lorazepam, it took an average of 260 minutes to return to baseline, whereas in patients receiving midazolam, it took more than six times longer to return to baseline. Lorazepam may be administered by bolus (0.05 to 0.1 mg/kg every 2 to 4

hours) or by infusion (0.05 mg/kg/h). Lorazepam is slightly less expensive than is midazolam.[91] It has been recommended as the BZD of choice for long-term sedation because of its more predictable recovery profile in sick patients in the ICU. Lorazepam for IV use has propylene glycol as a carrier. Risk of a metabolic lactic acidosis exists because of the metabolism of this carrier. Cases of fatal metabolic acidosis from propylene glycol have been reported in neonates taking a particular vitamin preparation. Several other potential ICU drugs may use propylene glycol as a carrier, including some IV preparations of phenytoin and phenobarbital, nitroglycerin, digoxin, and etomidate. Reports of propylene glycol toxicity in adults who received multiple propylene glycol infusions have been made.[92] Care should be taken when lorazepam is infused in patients who receive these other medications. In patients in the PICU, propylene glycol levels have been shown to correlate with the dose of lorazepam received; however, no metabolic abnormalities were detected.[93] Hemodialysis has been used successfully in the management of the lorazepam-associated propylene glycol toxicity.[94]

Benzodiazepines have been commonly used as the first-line treatment for pediatric patients with status epilepticus (SE); some earlier studies have indicated the safety of lorazepam over diazepam, and one study suggested that the use of IV lorazepam (0.1 mg/kg) is as safe and efficacious as IV diazepam (0.2 mg/kg) in pediatric patients with SE.[95]

Remimazolam

Remimazolam is a new benzodiazepine; it is a nonselective GABA-alpha agonist with high affinity to its receptor.[96-99] Remimazolam has no known off-target activities. Remimazolam structure is similar to midazolam (the parent compound) with the addition of the carboxylic ester linkage, which incorporates into it a pharmacokinetic profile similar to that of remifentanil.[100]

Remimazolam is an ester-based medication that is metabolized by rapid hydrolysis in the blood by nonspecific tissue esterases.[96,97,99] The product is an inactive metabolite (CNS 7054), which is a carboxylic acid, with very low affinity to the GABA-alpha receptor (more than 300 times lower affinity compared to remimazolam).[97,101] As a result, remimazolam provides a rapid onset of sedation, a short predictable sedation period, and a faster recovery in comparison to other benzodiazepines.[96-101] In one study of healthy adults, remimazolam reached its peak effect in 3 minutes. The duration and depth of sedation are dose dependant; greater sedation but quick recovery was noticed when using 0.075 to 0.2 mg/kg doses of remimazolam compared to a 0.075 mg/kg dose of midazolam in healthy adults.[97] Remimazolam has a rapid clearance (mean clearance of 73.3 ± 13.9L/h)[97,100] and a mean steady state volume of distribution of 34.8 ± 9.4L.[97]

Because of its dose-independent hydrolysis, its metabolism tends to follow first-order kinetics. There is no accumulation reported or anticipated in the recommended doses. This organ-independent elimination suggests the safety of using remimazolam in continuous IV infusion, with no anticipated residual sedative effects if high doses or prolonged infusions are needed.[97,99]

With these unique characteristics, remimazolam would be considered for use in procedural sedation (eg, upper and lower gastrointestinal endoscopies)[96-99] as IV continuous infusion or multiple boluses.[97-99] The hydrolysis to inactive metabolite

(CNS 7054) will allow for fast recovery with potential positive implications on patient satisfaction and early discharge. Remimazolam would also be considered for ICU sedation and premedication, especially in children before procedures or transportation to the operating room.

Similar to other benzodiazepines, remimazolam effects can be reversed by flumazenil.[97] Remimazolam has not yet been released to the market; there are undergoing phase II trials to evaluate its safety and efficiency, after its preliminary testing in humans showed favorable outcomes.[98]

The metabolisms of different BZDs are intertwined with each other. Most of the agents require an oxidative process first with potentially active compounds before glucuronidation and excretion. The pharmacokinetics for different BZDs is shown in Table 134.9.

Tolerance for and Dependence on Benzodiazepines

Tolerance for and dependence on BZDs can occur as with opiates in the PICU.[102] This effect is not all due to receptor number downregulation.[103] Withdrawal symptoms may be avoided with a slow taper of the medication of 10% per day or by substituting a long-acting oral agent such as diazepam. Acute withdrawal symptoms may include anxiety, insomnia, nightmares, seizures, psychosis, and hyperpyrexia. A postmidazolam infusion phenomenon has been described that includes poor social interaction, decreased eye contact, and a decreased interest in the surroundings. The patient may exhibit choreoathetotic movements with dystonic posturing that can persist for 2 to 4 weeks but will resolve with no sequelae. As would have been anticipated, the longer the duration and the higher the cumulative dose of benzodiazepines, the higher the chance that withdrawal symptoms will occur.

Flumazenil

Flumazenil is an imidazobenzodiazepine and is a specific competitive antagonist of the BZD receptor. It has no effect on other drugs such as barbiturates, ethanol, or other GABA-mimetic agents. Flumazenil reverses the hypnotic and sedative effects of BZDs. It has a half-life of approximately 1 hour after a single IV bolus. In patients with hepatic impairment, its half-life and clearance are prolonged, and a significant increase (>50%) of free drug occurs because of reduced plasma protein binding. Renal failure has little effect on the pharmacokinetics of flumazenil. It is indicated for the complete or partial reversal of the central sedative effects of BZDs. Contraindications include patients who have a known hypersensitivity to BZDs, patients with epilepsy who are receiving treatment with BZDs, and persons who have overdosed with a tricyclic antidepressant. The use of flumazenil is often associated with mild to moderate tachycardia and hypertension.

In cases of multiple drug overdose, the use of flumazenil remains controversial. It often is overused in the emergency setting without due concern for potential adverse reactions[104] because of the potential toxic effects (eg, cardiac arrhythmias or convulsions) of other psychotropic drugs ingested. The toxicity of tricyclic antidepressants becomes apparent as the effects of BZDs are antagonized. Patients should be evaluated for the signs and symptoms of a tricyclic antidepressant

overdose; an electrocardiogram (ECG) may be helpful in determining the risks involved.

The dosing information for pediatric patients is limited. The initial suggested dose is 0.01 mg/kg (maximum, 0.2 mg) with incremental doses of 0.005 to 0.01 mg/kg (maximum, 0.2 mg) given every minute up to a maximum cumulative dose of 1 mg. The lower doses are suggested for sedation reversal and the higher doses for BZD overdose. Infusions at 0.05 to 0.1 mg/kg/h have been used.[105] The use of flumazenil in sedated patients in the ICU should be tempered by the potential for an unrecognized BZD dependence, which would increase the risks of adverse effects. If its use is required, then a carefully titrated dose would be appropriate. The half-life of flumazenil is much shorter than that of some of the BZDs it may be counteracting (see Table 134.9). The use of an infusion may be necessary because re-sedation has been reported after single-bolus use.[106] However, this requirement should not preclude the use of flumazenil in an ICU setting.[107] Flumazenil has been used for the reversal of moderate sedation. The onset is usually within 1 to 2 minutes, with an expected peak effect at 6 to 10 minutes after IV injection[108]; both the plasma concentration of benzodiazepines and the flumazenil IV dose determine the duration of drug reversal. In the pediatric population, although it was well tolerated, it was not shown to significantly reduce recovery time.[109] Because flumazenil has a limited duration with the potential for re-sedation after discharge from medical care, an appropriate period of observation is required before discharge. A study in which researchers monitored the effects of flumazenil after sedation indicated that some of the residual effects of midazolam were still present after reversal.[110] Flumazenil also has been used to treat a paradoxical midazolam reaction[111] and has been shown to be effective in the management of hepatic encephalopathy or hyperammoneamia.[112] A Cochrane Collaboration review of articles pertaining to flumazenil use demonstrated a short-term improvement in hepatic encephalopathy. However, no improvement in recovery or survival was documented. No serious adverse effects were noted.

Chloral Hydrate

Chloral hydrate is a widely used oral hypnotic/sedative agent. It has been used for sedation in radiographic procedures, EEGs, and many health care locations. It was first synthesized in 1832 and used in 1869 as a hypnotic agent. Shortly after, reports of acute and chronic toxicity were published.[113] In 1910 it was labeled as the most dangerous of hypnotics, even though heroin and opium were in common use at that time. The addition of ethanol potentiates its effect (street name "Mickey Finn"). It has been used to control agitation in the intensive care nursery and to treat sleep difficulties in older patients.

Chloral hydrate is rapidly and completely absorbed from the GI tract and is immediately converted into the active component, trichloroethanol (TCE), by alcohol dehydrogenase.[114] The plasma levels peaks at 30 to 60 minutes. TCE is 45% protein bound. TCE undergoes glucuronidation with some oxidation to trichloroacetate (TCA). The half-life of TCE is 8 to 12 hours, whereas that of TCA is 67 hours. In infants and neonates this may be increased by a magnitude of three to four. With multiple dosing, a significant potential exists for accumulation. TCA can displace bound bilirubin from albumin. Its actions include CNS depression with drowsiness and sleep in less than an hour. With an overdose, the patient falls into a deep stupor

or coma, and the pupils change from contracted to dilated. At therapeutic levels, the blood pressure and respiratory rate are unaffected. Chloral hydrate has little hangover effect. It has several effects on the cardiovascular system including decreased myocardial contractility, a shortened refractory period, and an increased sensitivity of the heart to catecholamines. It also has effects on mucous membranes. Irritation can cause gastritis, nausea, and vomiting. With overdose, a severe hemorrhagic gastritis with gastric necrosis and esophagitis has been described. Chloral hydrate and ethanol interfere with one another's metabolism through competition for alcohol dehydrogenase. Also, ethanol inhibits the conjugation of TCE, and TCE inhibits the oxidation of ethanol. Coumadin activity may be increased by chloral hydrate. Chloral hydrate is synergistic with other sedative agents. In children receiving amphetamine-based medication, chloral hydrate is contraindicated because there have been rare reports of arrhythmias. The reversal of chloral hydrate with flumazenil has been described; however, a report of ventricular tachycardia with this combination also has been made.

Chloral hydrate is available as capsules, syrup (50 mg/mL), and suppositories. The sedative dose is 25 to 50 mg/kg (PO/by way of the rectum), whereas up to 100 mg/kg can be safely used in children younger than 5 years with a maximum dose of 1 g. Because of an increased half-life, neonatal dosing should be lower (25 mg/kg). In preterm babies, toxicity resulted when chloral hydrate was used for 3 days; in term babies, toxicity resulted when it was used for 7 days. The therapeutic level for TCE is 2 to 12 μg/L; toxicity occurs when the level is more than 25 μg/L. Chloral hydrate provides successful moderate sedation in approximately 90% of patients, but it appears to be less effective in patients older than 2 years. A higher risk of failure with excessive effect can be seen in patients with a history of obstructive sleep apnea or encephalopathy.

Signs of toxicity are usually noted within 3 hours of dosing. Paradoxical excitement also has been described in 6% of patients. There is some evidence that chloral hydrate may be genotoxic and carcinogenic. Mice studies have shown that a single-dose exposure can result in an increased risk of hepatic carcinomas and adenomas.[115] Chloral hydrate overdose produces a clinical picture that is similar to acute barbiturate poisoning. Ataxia, lethargy, and coma occur within 1 to 2 hours. Also, a pearlike odor may be noted. Cardiovascular instability poses the main threat to life. Severe arrhythmias including atrial fibrillation, supraventricular tachyarrhythmia, ventricular tachyarrhythmia, torsades de pointes, and ventricular fibrillation have been described. Chronic use can cause a dependence syndrome. Also, chloral hydrate is not detectable in the blood. TCE levels are measurable, but they are not useful for clinical management, although they can be helpful for retrospective diagnosis. The management of toxicity includes evaluation and monitoring at a medical facility if an amount greater than 50 mg/kg or an unknown amount has been ingested. Two capsules may cause significant toxicity in a toddler, so there is little room for error in the history. Charcoal with intubation should be considered if significant toxicity is suspected. Standard antiarrhythmic management is often unsuccessful, although esmolol, overdrive pacing, and hemoperfusion have been tried.

Other Agents for Sedation of the Pediatric

Intensive Care Unit Patient

Butyrophenones and Phenothiazines

Haloperidol

Butyrophenones belong to the group of major tranquilizers. Haloperidol is a potent antipsychotic agent with nonspecific dopamine antagonist action. It has little effect on the cardiovascular or respiratory systems. It produces the appearance of calm with minimal hypnotic effect and reduces operant behavior (purposeful movement). The patient appears tranquil and dissociated from surroundings but is readily accessible if spoken to. Haloperidol may mask actual feelings of mental restlessness. It is a potent antiemetic agent (with action at the chemotrigger zone) and has no appreciable effect on the EEG. It potentiates analgesics and other sedative agents. Compared with less potent butyrophenones, it has fewer adverse effects. Neuroleptanalgesia, a dissociative form of anesthesia, can be induced when haloperidol is combined with high-dose opiates. This anesthetic state is useful for certain cardiac and neurosurgical procedures that require cardiovascular stability and a responsive patient. It is metabolized to inactive compounds with a half-life of 15 to 25 hours. It is highly protein bound. Hepatic dysfunction increases the half-life because of reduced clearance. Adverse effects include extrapyramidal signs, although acute dystonia is rare. Prolongation of the QT interval is possible with the subsequent risk of ventricular tachycardia.[116] Hepatic toxicity can occur but is rare. Haloperidol is indicated for the treatment of psychoses, Tourette disorder, and severe behavioral problems in children. In the PICU it is used as a treatment for agitation in patients who are often unresponsive to other more commonly used agents. It also has proved to be effective as part of a sedative withdrawal strategy. Haloperidol is available as syrup, tablets, and an IM preparation. The usual dosage for agitation in children younger than 3 years is 0.01 to 0.03 mg/kg every 4 hours. The maximum daily dose is 0.15 mg/kg/day. Two IM preparations are available: The lactate is for repeated use, and the decanoate is a slow-release monthly formulation. Although not approved by the FDA, the IM lactate form has been given intravenously without problems.

Droperidol

Droperidol is faster acting than haloperidol with a shorter duration of action and a half-life of 2 hours. It is available as an approved IV formulation. With an IV bolus, mild hypotension occurs because of mild α-adrenergic receptor blockade. Droperidol is more sedating than haloperidol and may be used as a sedation adjunct to general anesthesia. It also is used in low doses (0.05 mg/kg) as an antiemetic agent. Concerns exist about the potential for droperidol to cause prolongation of the QT interval and result in ventricular tachycardia.[117]

Chlorpromazine

Chlorpromazine is a weaker antipsychotic agent with general CNS depressant activity. It has an antidopaminergic effect including extrapyramidal adverse effects, lethargy, and apathy with an EEG similar to that of normal sleep. It also causes a decrease in the body's ability to maintain temperature control, shivering is reduced,

and it can be useful in patients in hypothermic-induced states. Cardiovascular effects include α-adrenergic receptor blockade with hypotension and postural hypotension, but no effect is seen on the ECG. Respiratory drive and depth are unaffected; however, some dryness of the mucosa may be noted. In the GI tract, its anticholinergic effect causes a decrease in secretions and motility. Liver effects include jaundice, which occurs in 0.5% (recurrence rate, 40%), independent of dose or duration of therapy, and it is associated with a rash, fever, and eosinophilia. This syndrome has a low mortality rate and usually resolves quickly upon discontinuation of chlorpromazine. Other effects include antihistamine-like action; local analgesia; a temporary leukopenia; and, rarely, agranulocytosis. Chlorpromazine also has antiemetic properties. Indications include premedication, sedation as part of the lytic cocktail catheterization mixture number 3 (CM3),[118] intractable pain, antipsychosis, treatment of hiccoughs, prevention of succinylcholine pain, and induction of hypothermia (with other active measures). Dosing (0.05–1 mg/kg every 6 hours) may be via the PO, IM, IV, or rectal routes. Chlorpromazine is metabolized both in the gut wall and by the liver. It yields more than 50 metabolites, most of which are inactive.

Other phenothiazine derivatives include prochlorperazine, which has mainly antiemetic properties. Extrapyramidal adverse effects are more common in children younger than 5 years. Dosage is a PO or rectal dose of 0.4 mg/kg every 8 hours and an IM or IV dose of 0.15 mg/kg.

Lytic Cocktail

The lytic cocktail (CM3) is a mixture of 25 mg/mL of meperidine, 6.5 mg/mL of promethazine, and 6.5 mg/mL of chlorpromazine. Its recommended dose is 0.1 mL/kg of body weight, but significant institutional variations exist. The CM3 was popular as sedation for cardiac catheterization. However, CM3 has been reported to have a high failure rate and lacks several important characteristics of an ideal sedative for children. Dosing cannot be titrated easily and individually. Onset of action is delayed (30 minutes), and duration of effect is protracted (5 to 20 hours). CM3 has no anxiolytic or amnestic properties. Additional caution should also be exercised when this cocktail is used in children with seizure disorders. The metabolite of meperidine and the lowered seizure threshold from the chlorpromazine put the patient at risk. Patients with congenital heart disease with physiologic conditions such as a tetralogy of Fallot or left ventricular outflow obstruction may be put at risk because of systemic vasodilation that causes altered blood flow through shunts, a hypercyanotic spell, or decreased coronary blood flow due to diastolic hypotension.

Neuroleptic Malignant Syndrome

Both the butyrophenones and the phenothiazines have a rare but well-described adverse effect called the neuroleptic malignant syndrome. It is a cluster of adverse effects of antipsychotic medications first described in 1968. It involves the development of hypertonicity with autonomic instability, fever, and cognitive disturbance. The incidence is 0.5% to 1.4% of patients exposed to neuroleptic agents. The true incidence in children is unknown, however. Several different diagnostic

criteria are available. Fever and rigidity present in all cases; other symptoms are shown in Box 134.2. A variety of therapies have been described (Table 134.10).

Baclofen

Baclofen is a p-chlorophenol derivative of the GABA analog that has specific agonist activity at the $GABA_B$ receptor. It has a half-life of 2 to 6 hours. Baclofen has inhibitory effects on the brain and spinal cord. At the spinal cord level it suppresses spinal reflexes to result in muscle relaxation. It is widely used as a skeletal muscle

relaxant in patients with spasticity, such as cerebral palsy, spinal cord injury, and multiple sclerosis. It is most frequently given PO. Adverse effects include urinary retention, sedation, bradycardia, hypotension, respiratory depression, and apnea. Weakness may limit patient compliance. These side effects are sedative-like characteristics of the drug, which are not useful in clinical practice. Therefore abrupt cessation of long-term baclofen therapy resembles, in part, short-term sedative withdrawal.

Intrathecal baclofen (ITB) has been used with increasing frequency in children to treat spasticity. ITB was first introduced in 1984[119] with a pump delivery system that was available in 1992 for adults. This system allows delivery of the drug to the spinal cord and reduces the dose significantly (1% of oral requirements), limiting systemic adverse effects.[120] Baclofen inhibits the release of serotonin in the brain stem. After long-term use there is accommodation of the serotonin pathways to this long-term inhibition that is consistent with the usually observed increasing doses required for ITB during the first 12 to 18 months of treatment. When this inhibition is abruptly removed, sudden excess release of serotonin occurs. Acute overload of serotonin transmission, such as an overdose of serotonin reuptake inhibitors, can result in confusion, hyperthermia, myoclonus, and autonomic instability. It also has anticholinergic and antihistamine effects that may result in drowsiness; paradoxical excitation has been reported in children. More than 25 case reports[121] of ITB withdrawal have now been reported. ITB withdrawal seems to be more severe if the ITB treatment was for more than 1 year. A review of ITB pumps in 100 patients at a single center[122] has shown that problems with the delivery system are fairly common. Twenty-four percent of patients experienced a problem, with a follow-up period for a maximum of 5.6 years. An average of two problems per patient was reported. Disconnection of the catheter from the implanted pump was the most common problem. Access ports on the pump seemed to increase the risk of problems (16% compared with a 2% disconnection rate); however, these ports make troubleshooting easier. Causes of difficulty with ITB delivery are shown in Box 134.3.

Box 134.3

Causes of Interrupted Intrathecal Baclofen Delivery

Pump malfunction

Pump failure

Battery failure

Infections necessitating pump removal

Catheter problems (eg, kinks, holes, tears, dislodgement, disconnection, migration)

The ITB withdrawal syndrome is interesting because it appears to have many similarities with the neuroleptic malignant syndrome. Prolonged muscle contraction caused by rebound spasticity results in thermogenesis, hyperthermia, and rhabdomyolysis.[123] Patients with ITB withdrawal often are managed initially with broad-spectrum antibiotics as if they have sepsis and multisystem organ failure, with

no improvement in the clinical situation.[124] This treatment delays the diagnosis of ITB withdrawal. The differential diagnosis of the hypermetabolic state is listed in Box 134.4. The symptoms of ITB withdrawal can be classified into three categories (Table 134.11). Often the first clinical signs are the development of itching and some increase in spasticity. If replacement baclofen is not given, then the symptoms may progress to a severe hypermetabolic state that can be fatal if the cause is not recognized and treated. Of 27 patients reported to the FDA, 6 deaths were documented.[125] The management of ITB withdrawal requires early diagnosis. It involves supportive ICU care and the onset of baclofen replacement therapy as soon as possible. Box 134.5 provides a guideline for evaluating patients with suspected baclofen withdrawal. A definitive diagnosis may be obtained with measurement of cerebrospinal fluid baclofen levels, but the results probably are not going to be available in the time course of treatment initiation. Although the primary aim should be to replace baclofen, rapid replacement of ITB may not be possible. The required oral baclofen replacement dose may be 50 to 100 times the intrathecal dose, and patients do not tolerate this dose very well because of adverse effects. IV administration of a BZD should be the initial step in the treatment of baclofen withdrawal. Dantrolene has been used as an adjunct therapy for the increased spasticity.

Contact patient's intrathecal baclofen pump specialist to interrogate the pump and check the reservoir

Abdominal radiographs (anteroposterior/lateral) to check for catheter integrity

Neurosurgical consultation for possible surgical exploration and repair

If catheter appears intact on plain radiographs, consider performing a contrast catheter study to check for catheter integrity

If problem is unresolved, contact manufacturer

The use of the potent serotonin antagonist cyproheptadine has been proposed as an alternative treatment adjunct.[126] It improved fever, spasticity, and itching in adult patients with gout who had ITB withdrawal. Dosages of cyproheptadine were in the range of 0.25 mg/kg/day every 6 hours, either PO or IM. In some patients the ITB withdrawal is an elective management problem due to pump removal for infection. In these patients, if a replacement pump cannot be placed, the patient needs to be observed and managed in the ICU to recognize and treat the withdrawal syndrome. The monitoring of creatine phosphokinase (CPK) levels may be helpful in managing withdrawal. In the reported cases of ITB withdrawal, CPK levels have been in the range of 1800 to more than 40,000.[127] Mild elevations in CPK (300 to 500) may be an early marker of inadequate treatment.

Cannabis

The medical use of cannabis was first described in ancient Chinese history.[128,129] The real breakthrough happened in the mid-1960s, when the psychoactive component of cannabis—Δ9-tetrahydrocannabinol (Δ9-THC)—was discovered. This led to the formulation of other synthetic analogs of Δ9-THC and the discovery of the cannabinoids' receptors CB1 and CB2.[128,130] CB1 receptors are believed to regulate the neurotransmitters at the synaptic terminals both in the central and peripheral neurons. Centrally, CB1 receptors play an important role in movement control, pain and sensory perception, appetite, emotions, and autonomic and endocrine functions. This explains cannabis use in chronic and neuropathic pain control,[129] muscle spasticity, anorexia, sleep disorder, and some complex seizure disorders like Dravet syndrome, Doose syndrome, and Lennox-Gastaut syndrome. In a study

investigating the use of cannabidiol-enriched cannabis in pediatric patients with treatment-resistant epilepsy, 84% of patients were reported to have reduction or complete cessation of seizure activity while taking cannabis. More than two-thirds of the subjects were reported to have better mood, increased alertness, and better sleep.[131] These patients are frequently seen in the pediatric intensive care units for status epilepticus or breakthrough seizures; the use of cannabis in these patients may potentially reduce the need for frequent hospitalization and thus reduce the risk of all of the possible adverse events that could be related to the critical care environment.[132]

Peripherally, CB1 receptors have been identified in the gastrointestinal (GI) tract (intestine and liver), adipose tissue, and skeletal muscles. Cannabis has been used to control nausea in cancerous and noncancerous patients.[133] The presence of CB1 receptors in the GI tract and its promising use for antiemesis could suggest the use of cannabis in the treatment of some GI diseases like irritable bowel syndrome.

CB2 receptors are localized mainly in the immune system. They can be vital in cytokine-release regulation, inflammatory, and pain responses.[128]

Medical use of cannabis is legal in Canada and some US states. Further research is needed to understand the mechanism of actions of Δ9-THC and the nonpsychoactive compound, cannabidiol, and their interaction for optimizing potential therapy with the least adverse effects.

Dexmedetomidine

Dexmedetomidine (Precedex) is a selective α_2-adrenergic agonist. It has an effect at receptors in the CNS and peripheral nervous system, as well as in autonomic ganglia. Stimulation of the α_2 receptor decreases the release of norepinephrine, inhibits sympathetic activity, and produces sedation, anxiolysis, and analgesia. It is 1600 times more active at the α_2 receptor than at the α_1 receptor and is thus eight times more selective than clonidine. Clonidine has been reported as a sedative in the PICU.[134] Clonidine given enterally 5 mg/kg 4 times day was compared to placebo in 50 children. There was no difference in the opiate requirement, benzodiazepine requirement, sedation scores, or withdrawal between the placebo group and the clonidine. In this small study it is not clear if the clonidine dose was sufficient; further studies are required. In adults it has a redistribution phase of 6 minutes and an elimination half-life of 2 hours. The pharmacokinetics appears to be similar in the pediatric patient, even after a 24-hour infusion.[135] It is almost completely metabolized in the liver by glucuronidation and P-450 pathways to inactive metabolites. In patients with renal failure, the pharmacokinetics did not show any prolongation of the terminal half-life; however, these patients were sedated for longer after the infusion was terminated compared with the control group.[136] The prolonged sedation may be related to reduced protein binding of this normally highly protein-bound drug (94%) and thus higher free drug levels in the patient with renal failure. In patients with hepatic dysfunction, reduced clearance has been reported. With patients in severe hepatic failure, extension of the half-life to almost three times longer than normal was reported.[137]

Dexmedetomidine has proved to be effective for sedation in the adult intensive care setting.[138] Currently it is only licensed for 24 hours of sedation, although

approval for more prolonged use is pending. The recommended dosage for dexmedetomidine is a loading dose of 1 μg/kg over 10 minutes followed by an infusion of 0.2 to 0.7 μg/kg/h. It appears that in pediatric patients, the higher end of the dose range is required. Doses higher than 1.5 μg/kg/h have not been shown to provide any further sedative action. Advantages of dexmedetomidine include minimal respiratory depression and predictable hemodynamic effects. Because of the reduced sympathetic activity, blood pressure and heart rate fall slightly. Clinical sedation trials have shown a decrease in heart rate of 7% and blood pressure by 10%. It has been infused before, during, and after the extubation process. Hypotension and bradycardia are more likely to occur during the loading phase, which may need to be prolonged or interrupted. Dexmedetomidine cannot be given by rapid IV bolus because severe bradycardia as well as hypertension may occur as a result of direct stimulation of α_1-adrenergic receptors. Mild transient hypertension is sometimes noted in adults during the loading phase, although this effect was not noticed in pediatric patients. Long-term use of dexmedetomidine (160 hours) also has now been reported,[139] with no evidence of accumulation. The concern about rebound hypertension after long-term α_2-adrenergic agonist treatment, such as that occurring with clonidine, has not been reported. The prolonged use of dexmedetomidine is now common, and as such there is now growing evidence that withdrawal from dexmedetomidine must be considered.[140,141] Agitation, tremor, and sleep disturbances have been reported; however, many of the patients had received other sedative agents. It appears prudent to either wean the dexmedetomidine slowly if the infusion has lasted 4 days or more or else substitute a small dose of oral clonidine or the clonidine patch (harder to wean dose). It is possible to extubate on a lower dose of dexmedetomidine, which may reduce postextubation agitation and allow the wean to be completed during the child's ICU stay.

Sedation from dexmedetomidine often results in a patient who is tranquil yet easily aroused. Reduced analgesic requirements have been reported with its use. The easy arousal may make it a useful agent for when repeat neurologic examinations are required. Several articles concerning the use of dexmedetomidine in the PICU have been published. In a retrospective review of 121 patients from a mixed medical and surgical population in the PICU, a decrease of 20% in the dose of BZD or opiates was documented in 80% of the children who received dexmedetomidine.[142] Bradycardia (12%) and hypotension (16%) requiring intervention was described. In burn patients,[143] the overall quality of sedation was improved by the addition of dexmedetomidine; many patients also were able to be weaned from other sedatives during the dexmedetomidine infusion; loading doses were avoided to reduce the risk of cardiac complications. Dexmedetomidine use in pediatric cardiac ICU is gaining popularity. A retrospective review of dexmedetomidine use (infused >36 hours) in 35 postoperative pediatric cardiac patients did not show any significant changes in cardiovascular parameters, but a reduction in the postoperative opiate requirements occurred with an equivalent level of sedation.[144] Another study demonstrated less delirium in the postoperative cardiac child receiving dexmedetomidine.[145] Many of these patients had pulmonary hypertension and there appeared to be no concerns with the use of dexmedetomidine. Dexmedetomidine also appears to have antiarrhythmic effects that can treat and prevent arrhythmias in children. Its use postoperatively has been shown to reduce the incidence of postoperative cardiac arrhythmias.[146]

Further studies are still required to address questions regarding the metabolism, efficacy, and adverse effects of dexmedetomidine in the PICU population. This agent also has been safely used for a variety of noninvasive sedation procedures such as magnetic resonance imaging (MRI), and several cases have been reported of its use as an adjunct to general anesthesia for pediatric patients. It appears to be a useful agent in the management of opiate withdrawal. Furthermore, dexmedetomidine is useful for patients who are difficult to sedate, for the treatment of postoperative shivering, and for postanesthesia agitation. Procedural sedation with intranasal (IN) dexmedetomidine also has been reported (dexmedetomidine, 2 μg/kg IN, along with IN sufentanil, 1 μg/kg). Twenty children sedated with IN dexmedetomidine underwent dental restorative treatment without any complications. Sedation onset took approximately 45 minutes with a recovery time of about 1 hour.

Dexmedetomidine is not without adverse effects. It is contraindicated in patients with heart block, and bradycardia has been reported in an infant treated with digoxin who received dexmedetomidine during the infusion phase.[147] It also would appear prudent to avoid its use with other drugs that can reduce arteriovenous node function such as β-blockers and calcium channel blockers, as well as with patients who have severe ventricular dysfunction or hypovolemia, because reduction in sympathetic tone may cause a profound decrease in blood pressure. There are now several reports on the use of dexmedetomidine for toxidromes such as anticholinergic syndrome[148] as well as baclofen withdrawal in the PICU.[149]

Propofol

Propofol is a rapid-acting IV anesthetic agent. As a highly lipid-soluble 2,6-diisopropylphenol, it is an oil and is insoluble in water. It is formulated as a 1% aqueous emulsion (1.2% egg phosphatide, 10% soybean oil, 2.25% glycerol) with a propofol concentration of 10 mg/mL. Recovery from propofol is rapid because of its short redistribution half-life (α), and it is rapidly cleared by hepatic metabolism in healthy patients after short infusions, making it ideal for short procedures. The elimination half-life is 2 hours (Table 134.12), but the half-life is context sensitive and has been reported to be between 1 and 3 days after a 10-day infusion because of significant body accumulation. The kinetics follows a three-compartment model. The dose for induction of anesthesia in children is 2.5 mg/kg to 3.5 mg/kg; higher doses are required for infants and toddlers. Anesthesia also can be maintained by an infusion. The depth of sedation/anesthesia can be easily titrated, and an infusion rate of 25 to 150 μg/kg/min usually provides adequate sedation.

TABLE 134.12

Pharmacokinetics of Intravenous Anesthetic Agents

Drug	Elimination Half-Life (hr)	Volume Distribution (SS) (L/kg)	Clearance (mL/kg/min)	Protein Binding (%)
Etomidate	2.9	2.52	17.9	76.9
Ketamine	3.1	3.1	19.1	12
Propofol	1.9	2.3	30	96.8

SS, steady state.

As with most sedative agents, propofol has adverse effects that may be a concern

for the intensivist. It often causes hypotension in the sick child, and in patients dependent on high sympathetic tone to maintain normal blood pressure, even small doses of propofol may significantly decrease blood pressure. The hypotension is mainly caused by vasodilatation, and there is little direct myocardial depressant. Bradycardia also can occur upon the induction of anesthesia. Propofol increases atrial conduction time for neonatal rabbits and prolongs the refractory period. Propofol anesthesia can prevent the induction of known atrial tachycardias in the electrophysiology laboratory, and cases have been reported of conversion of atrial tachycardia to sinus rhythm upon induction of propofol anesthesia. Propofol is a potent respiratory depressant, and it has a useful depressant effect on airway reflexes, which may facilitate endotracheal intubation. The injection of propofol often causes pain, and in the alert patient, strategies to minimize this effect are useful. Most commonly, lidocaine, either mixed with the propofol or injected before the injection of propofol, will markedly reduce the pain.

Propofol sedation in the ICU has several advantages. It acts rapidly and produces an easily controllable level of sedation. Unlike the barbiturates, it provides rapid clinical recovery, even after prolonged infusion. It has antiemetic properties and can provide transient deep sedation if required for procedures. It also has been shown to facilitate sedative synergy with BZDs.[150] In the adult ICU population, propofol has been compared with midazolam for long-term sedation. Both agents provide good sedation, but propofol has the advantage of being more titratable with a faster recovery.[151] Despite the increased drug cost, the use of propofol can reduce overall ICU costs because of a reduction in ventilator weaning time.[152]

Propofol has been used in the ICU as an anticonvulsant for patients with refractory status epilepticus.[153] In a comparison with pentobarbital to provide burst suppression, both drugs were equally effective. Propofol was much more rapid in effect; no difference was found in outcome or ICU support measurements or length of stay.[154] In patients with raised ICP, propofol has the same effects on ICP and cerebral blood flow (CBF) and cerebral metabolic rate of oxygen as barbiturates. It also requires a similar level of hemodynamic support to maintain appropriate blood pressure and cerebral perfusion pressure (CPP). It can produce the same degree of burst suppression that may be required for uncontrolled intracranial hypertension. It also allows rapid changes in the level of sedation, to facilitate neurologic examination. In this regard it is a superior agent. As described later, however, the use of large doses of propofol in the ICU setting may be associated with worsened outcomes.

Special Issue Regarding Long-Term Infusion of Propofol

Several important problems may occur when propofol is used in the PICU. With long-term propofol infusions, a significant amount of lipid may be infused into the patient, with the same consequences as lipid infusions used for hyperalimentation. Hyperlipidemia and triglyceridemia have been reported in up to 10% of patients receiving propofol in the ICU. Pseudohyponatremia or the inability to do routine plasma electrolyte analysis has been described. It is important that the propofol calorie (20 mL/h = 528 kcal/day)[155] and lipid load be included in the patient's nutrition plan. It may be necessary to reduce enteral feeds or avoid intralipids in selected patients. With high propofol dosing, respiratory acidosis has been

reported.[156] The emulsion used for propofol administration is an excellent culture medium at room temperature; cases have been reported of patients with systemic infection caused by propofol during operative procedures.[157] This infection is due to poor aseptic technique in the preparation and use of the propofol syringes and infusion lines. Unusual infective organisms were detected in several patients, and an epidemiologic study by the Centers for Disease Control and Prevention found propofol to be the common element.[158] Certain precautions should be followed when propofol is used in the PICU. The staff should be educated to the potential dangers of infection from propofol. The ampule neck should be wiped with alcohol. There are no multidose vials of propofol. Syringes should be disposed of when they are more than 6 hours old, and lines should be changed every 12 hours. Filters are available that can remove many of the potential pathogens, and they are compatible with the lipid-based propofol infusion.

A few episodes of allergy to propofol have been reported; immune reactions, both anaphylactic and anaphylactoid types, are estimated at 1 : 45,000.[159] Although clinically indistinguishable, the anaphylactic response involves prior exposure to a component of the propofol suspension. Egg allergy has been considered a contraindication to its use. However, the egg phosphatide component found in propofol is not related to the major egg allergen protein ovalbumin.[160] In fact, intradermal testing with propofol in 25 patients allergic to eggs was negative; therefore current evidence suggests that anaphylaxis is not more likely to develop in patients who are allergic to eggs when they are exposed to propofol. Propofol does not release histamine and is an acceptable agent for use in patients with asthma.

Several new generic formulations of propofol are available. These formulations include different antioxidants, such as metabisulfites, which may have an increased risk of allergic reaction. However, this increased risk has not been borne out.[161] They appear to be equal in efficacy and adverse effects to the propofol solution known by the brand name Diprivan. A few patients who receive propofol may have dark green urine due to phenol metabolites; this effect is not a clinical concern.[162]

A new water-soluble prodrug, fospropofol, has been approved by the FDA and is approved for sedation procedures in adult patients. The fospropofol is hydrolyzed by alkaline phosphatases to propofol, phosphate, and formaldehyde. The half-life of fospropofol is 8 minutes.[163] The onset of action of fospropofol is significantly slower than for propofol (5 minutes), which reduces the incidence of hypotension and respiratory depression. The dose is about 6.5 mg/kg as a bolus,[164] and it is not recommended for infusion. However, fospropofol requires the same standards of care as propofol.

Propofol Infusion Syndrome

One of the most important concerns is the development of a refractory metabolic acidosis in children who had received propofol sedation in the ICU. This effect was first described in 1992 as a series of five cases[165] with fatal myocardial failure in children with respiratory illnesses requiring ventilation and sedation. Five young patients from different ICUs had croup and went on to have a refractory cardiac failure, bradycardia, and acidosis. A lipemic serum had developed in all patients. They had all received propofol at an average rate of about 8 mg/kg/h for more than 70 hours.

In review, the case reports were not as simple or as complete in their reporting, with several published letters[166] from physicians involved with these patients showing incomplete data in the reporting. Several other case reports of an apparently similar clinical course were then subsequently described in the literature, which was enough evidence for the Committee on Safety of Medicines in the United Kingdom to issue a warning on propofol and its use in pediatric patients. At that time the FDA could not find a causal link between propofol and the deaths in children and did not issue a warning.

This reaction to propofol came to be known as the propofol infusion syndrome (PRIS).[167] It is the sudden or relatively sudden onset of a marked bradycardia resistant to treatment with a least one of the following signs: lipemia, enlarged liver, severe metabolic acidosis, or rhabdomyolysis. PRIS is unlikely to be due to the carrier emulsion because intralipid has been used extensively in severely ill patients without problems. The propofol metabolites are acidic, highly water soluble, and have a short half-life.

A steady number of case reports of this syndrome have appeared in the literature since the initial description, as well as a couple of studies involving several hundred patients[168,169] who have not shown any problem with propofol in the PICU. In these studies, lower doses of propofol (4 mg/kg/h) were used, with regular monitoring of the acid base status and triglyceride levels. Propofol bashing became popular.[170] Few drugs are licensed specifically for the PICU, however, and proper trials are needed to avoid drugs being condemned as hearsay. Subsequently, a randomized controlled trial of propofol was initiated, and after the use of this drug in 327 patients, it was reviewed by the FDA.[171] The study was never published, but researchers found that, despite similar pediatric risk of mortality scores, patients who had received either 1% or 2% propofol preparations had a two to three times greater risk of death compared with the control sedative group. This finding led to a letter from AstraZeneca reminding health care workers that propofol was not approved for the sedation of pediatric patients.[172]

Much debate still occurs regarding whether there is a safe infusion rate or duration of infusion for propofol in the PICU setting. It has been estimated that a study to show a significant increase in death would require 7000 patients, which would be difficult to accomplish.

PRIS has also now been described in adult patients.[173] These patients had similar cardiac and metabolic findings, often associated with the management of intracranial hypertension. PRIS appeared to be a higher risk if the 2% formulation was used. Patients with raised ICP require deeper levels of sedation and require higher doses of propofol; they also receive vasopressor support to maintain the CPP, which puts a further stress on a myocardium that is already failing.

The pathophysiologic cause of PRIS is still poorly understood, but it appears to mimic mitochondrial myopathies. Patients are generally well until stressed. Rhabdomyolysis and cardiac and hepatic failure then develop in these patients.[174] Case reports have shown some metabolic abnormalities that may be the cause of the cardiac failure and acidosis. One report describes a 10-month-old child who had the syndrome and was successfully treated with hemofiltration and plasmapheresis.[175] Muscle and liver biopsy specimens showed changes consistent with a toxic insult. Analysis also showed a reduction in the cytochrome c oxidase activity in the muscle, with a normal activity in skin fibroblasts, excluding an underlying respiratory chain

defect. Profound acidosis with lactic acidosis is found in different types of genetically acquired cytochrome oxidase deficiency. It was postulated that the hemofiltration removed a water-soluble metabolite of propofol that had caused a reversible reduction in the oxidase activity. A second case report[176] also showed a metabolic abnormality. Elevated levels of malonylcarnitine and C5-acyl carnitine were found in a patient with PRIS. This patient was also treated successfully with hemofiltration. These findings are consistent with reports of impaired fatty acid oxidation due to impaired entry of long-chain fatty acids into the mitochondria and a failure of the respiratory chain. A review of the pathophysiologic function of the syndrome[177] suggested that propofol increases the activity of malonyl coenzyme A, which inhibits the carnitine palmityl transferase I, so long-chain fatty acids cannot enter the mitochondria. Propofol also uncouples oxidation, so the short- and medium-chain fatty acids cannot be used, even though they have entered the mitochondria and also may inhibit the respiratory-chain. Low energy production leads to cardiac and peripheral muscle necrosis.

In pediatric patients it has been suggested that an inadequate calorific intake coupled with a high metabolic demand requires a fully active fatty acid oxidation capacity. Propofol may inhibit this pathway and cause a cellular metabolic failure syndrome to develop. Children have lower glycogen stores and often require higher doses of sedative agents; thus the syndrome is more likely to occur in pediatric patients. A carbohydrate intake of 6 to 8 mg/kg/min should be enough to suppress fat metabolism in the critically ill child. Also, concerns have been raised about the influence of catecholamines and steroids in the development of the syndrome, especially in the adult population.

Propofol is still frequently used for procedural and short-term sedation,[178] but in a case report, researchers described a patient who had PRIS.[179] The patient had received a propofol infusion for 15 hours at 20 mg/kg/h. After a 13-hour propofol-free period, an 8-hour infusion of propofol at 4 mg/kg/h was given, after which the patient had intractable bradycardia and acidosis. This report raises concerns about high-dose, short-term propofol use in the PICU.

In a report on the use of propofol for two cases of refractory status epilepticus, patients aged 7 and 17 years had features similar to the PRIS.[180] Status epilepticus itself can result in neurologic deficit, hypoxia, rhabdomyolysis, cardiac arrhythmias, hyperthermia, metabolic acidosis, acute renal failure, and death. However, these patients received high doses of propofol (18 to 27 mg/kg/h) to achieve burst suppression for more than 48 hours. Rhabdomyolysis and cardiac failure developed in both patients. Neither lipid status nor acid base was monitored, and practitioners with limited experience with this drug used propofol as the sole agent. In light of the reports now appearing in the adult neurointensive care literature with the development of a propofol infusion–like syndrome in adult neurosurgical patients,[181] it would appear that propofol is not the best choice for prolonged sedation for patients with intracranial hypertension. An early indicator of the cardiac instability from PRIS may be changes in the ECG. It has been reported that the development of a right bundle-branch block with convex ST elevation was an early sign of this syndrome.[182]

Propofol remains a useful agent for procedural sedation in the PICU. When compared with midazolam and ketamine, propofol resulted in safe, effective sedation. The patients sedated with propofol awakened almost twice as fast; thus the

efficiency of the sedation service was also improved.[183] Propofol is also probably appropriate for overnight sedation, and higher doses should be avoided. It probably should not be used as a solo agent because in those cases tolerance appears to develop more rapidly. If its use is required for a prolonged period, then careful consideration should be given to its risks and benefits; prevention of PRIS should include adequate calorific intake. One study showed that staff members of some PICUs are still using long-term high doses despite the potential risks involved.[184]

The dose and duration of propofol should be carefully managed to minimize its use. It would appear from the reports of PRIS in the neurosurgical population that the desire for rapid awakening has propagated the use of propofol coma, rather than using barbiturates. There appears to be a significant mortality (50%) in neurosurgical patients who develop PRIS. Regular monitoring of the cardiac function, ECG, and CPK are warranted; lipid profile and acid base status may help in early detection. It has been suggested that daily CPK measurements will identify those at risk of developing PRIS and allow a change in sedation before the full-blown clinical effects become apparent.[185] When CPK >5000u was used as a screening tool, the incidence of PRIS in adult neurosurgical patients fell from 2.9% to 0.19%. Seven percent of these patients screened positive for PRIS, and their sedation was changed with no reported mortality. Although successful in this report, these steps may not necessarily prevent mortality from the syndrome.[186] Treatment should be immediate cessation of propofol. Cardiac support may be difficult because of unresponsiveness to conventional circulatory support. The use of pacing and extracorporeal membrane oxygenation has been reported. Hemodialysis or hemofiltration have been reported as having some success.

An outcome prediction table has been developed for PRIS based on more than 1000 reports from the FDA's Medwatch program, of which 20% involved pediatric patients.[187] The features associated with PRIS are shown in Table 134.13. In addition to the individual features, there were several additional scores depending on a combination of features (see Table 134.13). The predicted outcome from these scores is shown in Table 134.14. These predicted outcomes were very close to the actual reported mortality of the analyzed cohort. No independent verification exists at present. However, this article does highlight the variability in features of the PRIS and accounts for the differences in the reported mortality.

TABLE 134.13

Features Reported for Propofol Infusion Syndrome, Incidence, and Score

Feature	% Incidence	Score
Cardiac	44	1
Hypotension	34	0
Rhabdomyolysis	27	1
Hepatic failure	24	0
Renal failure	24	1
Metabolic acidosis	20	1
Dyslipidemias	5	0
Rhabdomyolysis and hypotension		1
Age <18 years and renal failure		–1
Rhabdomyolysis and renal failure		–1

TABLE 134.14

Predicted Outcome From Propofol Infusion Syndrome

Score	Predicted Mortality Rate (%)
0	10
1	25
2	50
3	75
4	90

The debate as to the safety of propofol in the PICU continues. Several reports state that use for short duration at low doses has proved to be safe,[188,189] starting at a low dose 0.5 mg/kg/h and limiting the maximum dose to 4 mg/kg/h. This approach, along with an infusion duration of 12 to 48 hours, has been reported as safe. However, these are small studies, and with an incidence that is unknown, a negative occurrence in a study of 200 patients still statistically means that the rate of PRIS could be up to 1.5%,[190] consistent with the data from the neurosurgical population. This leaves the intensivist with a difficult conundrum: Do I need to use propofol, or are there suitable alternatives for my patient?

Sedation and Analgesia for Procedures

Many procedures performed on children involve pain and anxiety. In many hospitals the administration of sedation and analgesia falls to the pediatric intensive care physician.[191] The pediatric intensive care physician needs to be familiar with guidelines and protocols that are used for moderate sedation outside the ICU setting. Procedural pain accounts for most of the pain experienced by children with malignancies,[192] and many pediatric patients with trauma will require sedation for procedures such as correction in the emergency department of fractured limbs and lacerations.

Conscious sedation, now commonly called moderate sedation or more appropriately procedural sedation, is a medically controlled state of depressed consciousness whereby the patient remains responsive to verbal stimuli or, at most, a gentle shaking of the shoulder.[193] It anticipates that protective reflexes will be maintained and that the patient retains a patent airway independently. Neither airway patency nor airway protection should be taken for granted because patients with conditions such as obstructive sleep apnea may obstruct their airway with little sedation and aspiration of food can occur even without sedation. Before moderate sedation is further explored, the insightful words spoken by Burton Epstein, in his 40th Rovenstine Lecture of the American Society of Anesthesiology (ASA) in the fall of 2002, should be considered: "The myth . . . of the achievability of a state of conscious sedation in which pediatric patients are simultaneously responsive to voice stimulus while immobile in the face of pain is just that—a myth."[194] A little consideration will reveal that for painless procedures, anxiolysis will most likely suffice, whereas for painful procedures, pharmacologic elimination of the response to pain will result in a need for general anesthesia. Between these two extremes, the use of local anesthetic agents may modify the response so as to allow potentially painful procedures to be performed during moderate sedation. Another factor to consider is the effect of variation in the level of stimulation, whereby sedation titrated to effect during a painful stimulus becomes excessive once the stimulus is completed. Thus the practitioner treads on a narrow and sometimes impossible

pathway when giving moderate sedation. The state of moderate sedation is part of a continuum (Table 134.15) defined by the working groups of the American Academy of Pediatrics (AAP) and the ASA,[195] which encompasses a range from anxiolysis to general anesthesia that is appropriate for surgery. This continuum is difficult to control, and staff administering moderate sedation must be able to appropriately manage any patients who enter a deeper level of sedation than that planned. The goals of sedation are shown in Box 134.6. It is helpful to think of moderate sedation as consisting of several components. A balanced sedation technique will involve amnesia, analgesia, relaxation, and inattention. Different procedures require different degrees of these components (Table 134.16).

TABLE 134.15

States of Altered Consciousness

Designation	Description
1	Minimal sedation (anxiolysis)
2	Moderate sedation/analgesia (conscious sedation)
3	Deep sedation/analgesia
	General anesthesia

Paracentesis	1	3	0	2
Burn dressing	2	4	0	2
Local anesthesia	3	2	2	3

MRI, magnetic resonance imaging.

Types of Procedures and Preprocedure Evaluation

In many instances sedation may be beneficial in the PICU, such as for the placement of central lines and centesis tubes and during dressing changes. Sedation facilitates the procedure in uncooperative patients and allows long or uncomfortable

procedures to be performed. Outside the ICU, both noninvasive and invasive radiologic examinations[196,197] often require sedation (Box 134.7).

Box 134.7

Nonintensive Care Unit Procedures Requiring Sedation

Cardiac catheterization: diagnostic, angioplasty, stents, valvuloplasty, closure devices

Neuroradiology: angiograms, stents, embolization

Ultrasound: transesophageal echocardiography, drainage procedures

Computed tomography scan–guided abscess drainage

Safety with moderate sedation is largely determined by careful assessment and management of the airway, together with precautions to prevent aspiration of gastric contents. Adequacy of sedation largely depends on appropriate patient selection, the combination of the patients' known medical conditions, past sedation experience, and the nature (particularly pain) of the patients' procedures, coupled with appropriate drug selection. Moderate sedation may be better tolerated than deep sedation or general anesthesia when hemodynamic stability is compromised because many sedative and anesthesia agents induce cardiovascular instability such as vasodilation or myocardial depression. Furthermore, the ability to monitor the patient's neurologic status during the procedure through conversation or instruction may be helpful, especially during invasive neuroradiologic procedures. Moderate sedation may allow an earlier discharge because less sedative is being used and may make the procedure, which would usually require the full operating room environment, possible outside of the operating room.

All patients should be assessed before moderate sedation. Box 134.8 lists the elements that should be included in the assessment. The medical history should include evaluation of the cardiorespiratory system, any history of gastroesophageal reflux, and any previous sedation attempt that failed or any abnormal reaction to sedation. An asthmatic attack or respiratory tract infection, poorly controlled seizure disorder, or diabetes may require a change or postponement of the sedation plan. It is recommended that patients be classified according to the ASA preoperative patient classification (Table 134.17). In most circumstances it is generally recommended that patients in ASA class VI and some in class III are not suitable for moderate sedation.

TABLE 134.17

American Society of Anesthesiology Classification

Class	Description
I	A normally healthy patient
II	A patient with a mild or well-controlled disease state
III	A patient with a severe or poorly controlled disease state
IV	A patient with a severe disease state that is a constant threat to life
V	A moribund patient who is not expected to survive without surgery

It is prudent to adopt the same guidelines that are used before general anesthesia is administered, in case sedation that is deeper than anticipated occurs. These guidelines are age dependent, and current recommendations are shown in Table 134.18. Despite this consideration, less caution is often reported regarding fasting, without any apparent worsening of outcome. For example, in a survey of 450 radiology departments, 35% had no nothing-by-mouth (NPO) status requirement for neonates, and 17% used a 2-hour NPO status requirement for infants. For oral contrast studies, most departments sedated the patient within 1 hour of the contrast being swallowed.[198] Consent should be obtained as with any medically indicated procedure or intervention. It should include discussion about the risks and benefits of the procedure and the sedation technique, as well as expectations of outcome and alternatives to the procedure and sedation.

TABLE 134.18

Presedation NPO Guidelines

	Solids/Nonclear Liquids[a]	Clear Liquids[b]
Adults	6 h	3 h
Children	6 h	3 h
Neonates (<3 mo)	4 h	2 h

[a]Milk, breast milk, pulp fruit juices.

[b]Clear fruit juices, water.

NPO, nothing by mouth.

The presedation interview for outpatients or non-ICU patients also should involve giving instructions and information to a responsible person, including postsedation instructions, a 24-hour phone contact phone number, guidelines concerning limitations of activity, and expected postsedation behavior. If moderate sedation is provided for nonscheduled patients, a review of several aspects is important (Box 134.9).

Hypovolemia is manifest when sympathetic tone is decreased

Fasting

Time of last meal

Trauma-induced delay in gastric emptying

Drug-induced delay in gastric emptying

Monitoring During the Procedure

Sedation provided outside the ICU should be performed in a facility/area with the appropriately trained support staff. The staff should have had appropriate training with respect to pharmacology, monitoring, resuscitation (basic and advanced life support), emergency drugs, and cardiac arrest protocols and medications. Advanced cardiac life support and pediatric advanced life support recommendations should be available to be followed.

Monitoring of patients undergoing moderate sedation is an important component of safe, effective sedation. Several different recommendations have been made by the Joint Commission on Accreditation of Healthcare Organizations,[199] the American Board of Anesthesiology, and the AAP. These recommendations have not yet been fully followed by persons providing sedation for children.[200] A study of pediatric dentists conducted after the AAP published its new recommendations found

minimal monitoring and documentation of the sedation procedure. Obtaining baseline vital signs is important. Because of the possibility of oversedation, the level of consciousness should be assessed frequently, especially during titration of effect. This level of consciousness is best assessed with the Ramsay scale (see Table 134.1). A sedation record is important for documentation of the drugs used with times and doses and for the monitored measurements that are charted on a time-based record. Monitoring should include pulse oximetry to assess the degree of oxygenation and heart rate. The saturation should be maintained by supplemental oxygen. Breathing can be assessed either by monitoring the respiratory rate or by capnography. The blood pressure should be checked at regular intervals during the procedure. A study of 85 pediatric patients with complications after sedation showed that most severe complications resulted from a common pathway involving respiratory depression leading to respiratory arrest, cardiac arrest, and subsequent severe neurologic devastation. The most common causes for these complications are summarized in Box 134.10. There is no particular drug that is more likely to cause problems. Polypharmacy, especially with three or more drugs, has been shown to be a risk factor for pediatric sedation complications.[201] Dentists using nitrous oxide in combination with other agents appeared to have a higher incidence of problems. If long-acting drugs are used, the patient must be observed for an appropriate length of time. Several reports have been made of respiratory arrest occurring while the child was in the car seat on the way home. Any health care worker providing moderate sedation should be familiar with an emergency algorithm in case problems arise (Fig. 134.4).

Many pharmacologic options are available for moderate sedation in children. The oral route is commonly used because it has a slow onset time that avoids a rapid peak effect, but it also gives an unpredictable degree of sedation, which is not easy to titrate. The rectal route is nearly always available and has found favor in the past for barbiturate sedation. More contemporaneously, rectal diazepam at 0.2 to 0.5 mg/kg has proved useful in controlling seizures when IV access is not available.[202] Onset can be fairly slow and the duration prolonged. Intravenous sedation is considered the gold standard route: It is effective, it can be titrated to effect rapid onset, and there is a lot of experience with this method among health care providers. However, establishing an IV access in a child can be challenging, and there are many minor procedures that do not necessarily require IV sedation. The risk of inadvertent overdose is also higher using the IV approach. Intramuscular injections have been used as well,[203] but there is a delay in onset, it is painful, the practitioner will be unable to titrate to effect, and it might delay recovery; however, this method is useful in very uncooperative patients for whom IV placement is not feasible.

Intranasal drug delivery is now recognized as a useful and reliable alternative to oral and parenteral sedation. Intranasal administration of medicines for symptomatic relief, prevention, and treatment of topical nasal conditions has been widely used for a long time.

Intranasal administration of sedative medications has emerged as an alternative to oral and parenteral routes since the early 1990s.[204-206] Table 134.19 shows some of the advantages and disadvantages of IN sedation.

TABLE 134.19

Intranasal Sedation Advantages and Disadvantages

Advantages	Disadvantages
Quick onset of sedation	Some diseases/processes can affect the absorption
Noninvasive and less painful than injectable routes	Medication cannot be delivered with big volume
Ease of drug delivery	Medication might be swallowed or spat out
Favorable tolerability profile	Medications must be available in a suitable concentration
Closer proximity of the nasal mucosa to the brain	
Lack of necessity for sterilization	

Certain medications benefit from intranasal administration, such as those with poor stability in gastrointestinal fluids, those with poor intestinal absorption, and those with extensive hepatic first-pass elimination, which reduces the bioavailability of the drug and leads to unpredictable blood levels after oral administration. Lipophilic medications are usually well absorbed from the nasal cavity mucosa, and often the IV formulation is used.

There are several preparation properties that can improve intranasal efficacy. A higher formulation viscosity allows for better drug absorption as a result of increased contact time between the drug and the nasal mucosa. The pK_a of the drug and the pH of the absorption site and the drug are also important. The ideal pH of the drug formulation is between 5 and 6.5; pH values less than 3 or more than 10 may cause damage or pain.

There are two methods of intranasal administration. With the drop technique, a syringe is used to slowly drop the medication into the nares of a supine child. It is the simplest method; however, it may be difficult to predict the actual dose administered due to possible swallowing or spitting out of the medication. The child may also cough or sneeze,[207] resulting in an unpredictable medication loss. Alternatively, the mucosal atomizer device (MAD) can be used. This device atomizes the medication into particles that are the optimal size for deposition across the broad area of the intranasal mucosa (Fig. 134.5).[208]

FIG. 134.5 Device used for delivery of atomized medication.

Various sedative medications have been successfully reported to provide sedation when administered intranasally. Midazolam is the most commonly used IN medication. The dose ranges between 0.2 and 0.7 mg/kg (maximum dose usually about 10 mg). To reduce the volume of the medication, a 5-mg/mL solution is most frequently used. The onset time is about 10 to 15 minutes. Unfortunately, intranasal midazolam often causes discomfort on administration.[208-210] This is believed to be due to the acidic pH of 4 of the IV solution that is used. Several methods have been tried to minimize the irritation with variable results, such as mixing lidocaine with midazolam, elevating the pH to more physiologic levels; this last method was not very successful, as midazolam precipitates in water if the pH is >4.6. Sufficient

midazolam plasma concentrations to induce moderate sedation were shown to be rapidly achieved after IN administration to healthy individuals.[206] Aerosolized buccal midazolam has been reported to provide effective sedation for laceration repair.[208]

Sufentanil use intranasally has been reported in the emergency room and for pediatric dental procedures alone and in conjunction with IN dexmedetomidine.[210] The doses range from 1 to 2 mcg/kg (maximum dose 20 mcg). Using a 50 mcg/mL solution along with its high potency results in an drug volume about 0.5 mL, which is deemed appropriate for intranasal administration with respect to improved efficacy, and reduced discomfort.[210] The onset time is also quick, about 10 to 15 minutes with duration of about 30 minutes. Higher doses have been associated with respiratory depression, and nausea has been reported, which can be effectively managed using sublingual ondansetron.

There are a few limited reports on the use of intranasal remifentanil. Doses of 2 to 4 mcg/kg have been used. Onset time is less than 5 minutes and duration of effect appears to be about 10 to 15 minutes. Multiple administrations may be required. Fentanyl use has been described in few studies; it was used as the only agent using a patient-controlled administration during childbirth[211] or with other medications for procedural sedation in the emergency room.[212] However, when compared dose for dose with sufentanil, much larger drug volumes are required, which may limit its usefulness.

Dexmedetomidine has been used intranasally with doses of 1 to 2 mcg/kg.[213] It has a slower onset time of about 45 minutes. Sedation appears equal or better than that of oral midazolam. The duration of effect is also longer than other intranasal sedatives. Procedures lasting over an hour have been reported. Ketamine has also been used via the IN route.[207] The reported dose was 5 to 9 mg/kg.[214] It provided more effective sedation than IN midazolam, without any evidence for hemodynamic instability.[215] It has also been shown to be a safe and effective method of sedating children for dental procedures.[207]

Both flumazenil and naloxone can be given via the intranasal route. It has been shown that 40 mcg/kg of IN flumazenil provides a therapeutic plasma level of 10 to 30 ng/mL and a peak level of 68 ng/mL within 2 minutes.[216,217] A dose of 100 mcg in each nostril is believed to be simple, easy to memorize, and effective in most children. This dose can be repeated as necessary. IN naloxone has been described as well; there are no pharmacokinetic studies in humans, but the bioavailability of IN naloxone in rats was found to be equivalent to intravenous naloxone.[218] In one study, the proposed dose is 0.2 mg in each nostril.[216] The dose can be repeated as needed based on the clinical response.[216,218]

Another route of administration is transmucosal administration, such as the fentanyl *lollipop* (ACTIQ). Dosing recommendations are shown in Table 134.20. One must always keep in mind that BZD-opiate or barbiturate-opiate combinations are potent causes of respiratory depression, and extra monitoring and vigilance should be used. With IM and oral medications, adequate time should elapse to allow absorption before a further dose is given to avoid accidental overdose.

TABLE 134.20

Drug Dose Guidelines for Moderate Sedation

Route	Drug	Dose
PO	Chloral hydrate	50-75 mg/kg (repeat 25 mg/kg)
	Diazepam (Valium)	0.2-0.4 mg/kg (max, 20 mg)
	Midazolam (Versed)	0.5-0.75 mg/kg (max, 20 mg)
IM	Pentobarbital (Nembutal)	4-6 mg/kg (max, 100 mg)
	Fentanyl (Sublimaze)	1-3 μg/kg
	CM3	0.08-0.1 mL/kg (max, 2 mL)
IV	Morphine	0.1 mg/kg
	Meperidine (Demerol)	1-2 mg/kg (max, 75 mg)
	Fentanyl (Sublimaze)	1-2 μg/kg (max, 5 μg/kg)
	Midazolam (Versed)	0.05-0.1 mg/kg
	Diazepam (Valium)	0.05-0.1 mg/kg

CM3, catheterization mixture number 3; *IM,* intramuscular; *IV,* intravenous; *PO,* by mouth.

As noted in Table 134.16, different procedures require different qualities of sedation. These qualities are found in the array of drugs available to the intensivist (Table 134.21). It may be useful to choose the sedative agent or agents that best fit the particular requirements for the procedure being performed.

TABLE 134.21

Sedation Quality: Different Drugs

	Amnesia	Analgesia	Relaxation	Inattention

Ketamine	2	4	0*	4
Nitrous oxide	3	3	1	3

*May antagonize other drugs having this effect.

0, possible effect.

Opiate and BZD antagonists should be readily available wherever moderate sedation is being performed. Staff caring for these patients should understand the drug indications and dosing of these medications to reduce any potential delay in their appropriate use. They can quickly and effectively reverse the respiratory depression from excessive doses of sedation.

In some circumstances the services of the anesthesia department may be useful. The anesthesia department has access to other pharmacologic agents such as propofol and nitrous oxide, as well as the inhalational agents. The ability to use a deeper level of sedation if required is easily obtained with these rapidly acting, short-acting agents. In emergency procedures where the patient's NPO status is unsafe or unknown, patients may need to undergo intubation to protect the airway.

Anesthesiologists have the ability to perform a “needleless” sedation technique using a gas induction with anesthetic agents; an IV drip may be placed if required when the patient is asleep. This technique is especially useful for repeat procedures in oncology patients. Also, anesthesia personnel are better able to sedate a patient whose illness may contraindicate routine moderate sedation protocols (Box 134.11).

Box 134.11

Patients Unsuitable for Moderate Sedation

Premature (<60 weeks' gestation)

Apnea, respiratory, or cardiac monitor at home

Airway obstruction

Bronchopulmonary dysplasia, chronic obstructive pulmonary disease, recent pneumonia, or croup

Uncontrolled seizures or multiple medications

Multiple psychotropic medications

Poorly controlled asthma

Vomiting

Gastroesophageal reflux disease

Raised intracranial pressure

History of difficult sedation

Postprocedure Care and Monitoring

Care of the patient during the recovery period after moderate sedation is important. Patients must be monitored during recovery to ensure that adverse events are rapidly recognized and treated. The recovery area should be equipped with appropriate monitors and resuscitation equipment and have a trained individual in attendance. The monitoring should be performed to the same degree as during the actual procedure. Level of consciousness and vital signs should be recorded at regular intervals. A physician who is responsible for the patient must be identifiable and must be easy to contact if required urgently. Patients may be discharged home when they are alert and orientated or when they have returned to baseline if baseline initial mental status was abnormal. Vital signs should be stable and within acceptable limits. A sufficient time should have elapsed if a reversal agent was used (2 hours). Patients should be discharged in the presence of a responsible adult to accompany them home and report any complications. Written instructions should be given to the parent concerning diet, medications, and activities, and a 24-hour contact telephone number also should be given to the parent.

Moderate sedation is safe and frequently used; unconscious sedation is potentially hazardous, and patients who undergo it require careful monitoring. Hospital protocols are useful for a smoothly run, safe sedation policy.[219] Staff should be appropriately trained in sedation and resuscitation basic and advanced life support. When the ASA/AAP recommendations are followed, the risks of a sedation-related complication can be reduced.[220] Individual risk factors include deep sedation and the use of chloral hydrate. When all the recommendations for moderate sedation, including NPO, ASA class, avoidance of deep sedation, sedation level monitoring, and drug use were followed, the adverse event rate was zero.

Sedation for Magnetic Resonance Imaging

The PICU physician is often called on to provide sedation for a patient in the ICU who is undergoing MRI. Also, many institutions rely on the PICU team to provide a sedation service for other inpatients or outpatients undergoing MRI. Deep sedation is often required for effective sedation of younger children undergoing an MRI scan. The same standards as applied with any other child undergoing sedation should be adhered to[221] with respect to patient selection, monitoring, and postimaging care.

Magnetic resonance imaging is being increasingly used to aid in the diagnosis of neuroanatomic disorders. The patient is required to lie still within a small space while multiple images are obtained. MRI scanning is performed less rapidly than computed tomography (CT) scanning. Movement by the patient degrades the image quality, and a change in the patient's position may affect the homogeneity of the magnetic field, which is optimized at the beginning of the scan. Studies can take from 45 minutes to more than 2 hours, with individual sequences taking 3 to 10 minutes. The scanner is noisy and the restriction on space and movement can induce claustrophobia in some patients. The patient also may experience a slight increase in temperature. Most adults and children older than 6 years are capable of lying still for the scan. With the use of earplugs and music, it is well tolerated. Several groups of patients, however, may require sedation[222] for the scan to be performed (Box 134.12).

Box 134.12

Indications for Sedation for Magnetic Resonance Imaging

Very young or agitated patient

A prolonged study (multiple scans)

Anxiety

Claustrophobia

Intensive care patient

(Not a complete list.)

Because of the large magnetic field, several unique problems[223] can occur during a scan. These problems include the potential risk of the magnet causing a ferromagnetic object to move or heat up or the induction of an electric current from the radio frequency pulses and switching magnetic gradients used in generating the images. This potential risk results in a significant list of contraindications to MRI (Box 134.13). Sedating these patients also entails several risk factors. The patient is in a remote location, with limited access to and visibility of the airway. Several equipment issues exist as well (Box 134.14). The monitors used must be suitable for use in the MRI suite.[224] They should be nonferromagnetic; the cables should be screened from electromagnetic interference (fiberoptic is ideal); and the signal should be filtered to avoid radio frequency interference (which interferes with image quality). Despite the specialized technology available, several problems remain. The ECG waveform is frequently altered, and information regarding analogs is often

lacking during a scanning cycle. The ECG cables may cause burn injury, and special ECG electrodes are required to avoid this occurrence. For pulse oximetry to be performed, a special probe is required. Heating of the usual probe may cause burn injury. A fiberoptic connection to the patient is best. Capnography requires long tubing, which results in a prolonged upsweep and delay in displaying real-time measurements. The respiratory rate and trends can still be useful. Any battery-powered monitor requires a nonmagnetic lithium battery. Exposure to the MRI shortens battery life. Most ICU ventilators are not MRI compatible (Servo *i* is available as an MRI compatible model). Some specialized MRI-safe anesthesia machines have a ventilator; however, their use should be restricted to the anesthesia staff who are familiar with the equipment. The IV poles and the equipment carts also should be nonferromagnetic. Any equipment with a transformer (eg, syringe pumps and IV pumps) must be kept out of the magnetic field. Gas cylinders must be aluminum. The area around any magnet that generates a magnetic field stronger than 5 G should not contain any ferromagnetic items.

Box 134.13

Contraindications to Magnetic Resonance Imaging

Cardiac pacemaker

Aneurysm clips

Automatic implanted cardiac defibrillator

Neurostimulator

Pacing wires

Cochlear implant

Implanted insulin pump

Penile prosthesis

History of ocular injury involving metal object

History of vascular surgery <3 months

History of soft tissue metal foreign body <3 months

History of orthopedic hardware <3 months

(Not a complete list.)

Box 134.14

Potential Difficulties in Magnetic Resonance Imaging

Malfunction of anesthesia or sedation equipment

Malfunction of monitoring

Anesthesia or sedation equipment causing interference with image quality

High-velocity ferromagnetic projectile from loose object

Disruption of electronic devices

Any staff entering the MRI suite should remember to remove any ferromagnetic objects, including keys, watches, pens, and credit cards. Stethoscopes and laryngoscopes also are ferromagnetic. Infusion pumps should be outside the magnetic field—that is, outside the 5-G line. The electric motor in infusion pumps emits electromagnetic radiation and may run at an abnormal speed in the presence of a strong magnetic field. The pump is also a projectile risk. IV infusions through long tubing from outside the scanner can be useful so that the depth of anesthesia can be altered without having to enter the MRI suite. MRI-compatible infusion pumps are now also available. Some of these pumps allow changing infusion rates via electronic handheld devices without the need to enter the scanning room. The ICU patient's infusions can be changed over to these infusion devices while the patient is still in the ICU and then transported to the scanner.

The use of a cuffed endotracheal tube may affect the quality of the MRI image because of metal in the valve of the pilot balloon and reinforcement of the mask airway. With the patient in the ICU, special care must be taken to ensure that all cables and transducers that may be carefully screened and all ferromagnetic objects are removed ("hiding in the sheets"). For invasive vascular pressure to be measured, the transducer should be as far from the patient as is practically possible and separated with a saline-filled pressure line. If cardiac arrest occurs, the patient should be removed from the magnetic field. The defibrillator should be kept outside the magnetic field and checked regularly. A nonferromagnetic code cart is also advisable. It is essential that the code team follow the rules about removing any loose magnetic items before entering the MRI suite or else a lethal projectile may be released. The ICU patient's lungs are frequently hand-ventilated by ICU staff in the MRI suite. The sedation technique is often a continuation of that used in the ICU, especially for a patient who undergoes intubation. In some children, single doses of fentanyl or midazolam may be sufficient for a adequate sedation. If deeper sedation is required for patient comfort/cooperation, then IV sedation with supplemental oxygen with propofol is useful. A bolus of 2 mg/kg and an infusion of 100 μg/kg/min are useful for patients with few medical problems and an easily maintained airway. It results in a rapid recovery with little nausea or vomiting.

Specific Drugs for Sedation

Ketamine

Ketamine is a phencyclidine derivative that provides sedation and analgesia. It results in a state of dissociative (trancelike) anesthesia. It is available in a variety of dilutions, such as 10 mg, 50 mg, and 100 mg/mL. The latter is the most beneficial for

IM use and the preparation of infusions. For a state of general anesthesia to be induced, a dose of 2 mg/kg IV is required. Onset takes 1 to 2 minutes with anesthesia lasting 10 to 15 minutes. Lower doses may be used for sedation. Anesthesia also can be induced by the IM route with a dose of 10 mg/kg, although onset is slower (5 to 10 minutes) and duration of prolonged effect is 45 to 60 minutes. It is metabolized by the liver and excreted by the kidneys. The half-life is 3.1 hours (see Table 134.12).

The adverse effects of ketamine include hypertension, tachycardia, increased intracranial pressure, and bronchodilation. The bronchodilation is probably due to its sympathomimetic action. It is a direct myocardial depressant, but blood pressure is usually maintained by the sympathetic stimulation that ketamine causes. In critically ill patients who already are using their maximum sympathetic drive, ketamine may cause a decrease in cardiac output or even cardiac arrest.[225] Hallucinations and other psychiatric symptoms are often reported during and after its use in adults, but they occur less frequently in children. Ketamine is a potent sialogogue, and the use of an anticholinergic agent such as glycopyrrolate may be helpful. Its use is contraindicated in patients who cannot tolerate hypertension,[226] have a history of cerebrovascular hemorrhage, have psychiatric disturbances, and have raised ICP. It is a useful agent for sedation, especially if there is no IV access. It has been used in patients with status asthmaticus as an adjunct bronchodilator both in intubated and nonintubated patients at an infusion rate of 0.5 to 2 mg/kg/h. After discontinuing its use, the patient should receive BZDs to minimize the likelihood of hallucinations and be nursed in a quiet environment. Ketamine cannot be assumed to preserve pharyngeal reflexes any better than other sedatives agents, and apnea and airway obstruction can still occur.[227] NPO guidelines should still be observed. Ketamine is sometimes given with propofol *(ketofol)* for procedural sedation in the belief that this combination may be a safer, better sedative technique. However, when compared[228] there were more episodes of desaturations related to respiratory depression and airway episodes such as laryngospasm in the ketofol group compared to the group given propofol alone.

Ketamine has been shown to be effective for refractory status epilepticus (RSE). During RSE there is a down-regulation of the $GABA_A$ receptors limiting the effectiveness of the benzodiazepines. There is, however, an upregulation of NMDA receptors during RSE, which promotes excitotoxicity and further potentiates epileptogenicity.[229] On review of the literature, ketamine was effective in 67% of cases with RSE (presumed significant underreporting error), at doses up to 3 mg/kg hour and infusions lasting 27 days. There is at present only grade 4 evidence for its use in RSE; however, it should be considered especially as its cardiac profile may be advantageous compared to other anesthesia agents used.

Etomidate

Etomidate is a carboxylated imidazole that is unrelated to other anesthetic agents. It is a rapidly acting IV anesthetic agent, which, like other rapid-onset anesthetic agents, partitions into the brain within one circulation time and redistributes out of the brain over the next few minutes. Its hypnotic action involves the $GABA_A$ receptor. It is available dissolved in 30% propylene glycol as a 2-mg/mL solution. Like propofol, it causes pain on injection. The anesthetic dose is 0.2 to 0.3 mg/kg. It has a favorable adverse effect profile with minimal cardiovascular and respiratory

depression. Etomidate is associated with a high incidence of nausea and vomiting after emergence from anesthesia. Its pharmacokinetics is shown in Table 134.12. The greatest disadvantage of etomidate in the intensive care setting is adrenocortical depression due to its potent inhibition of adrenocortical mitochondrial 11-β-hydroxylase.[230] This effect is present in neonates and in adults.[231] The inhibition can last for 24 hours after a single dose of etomidate,[232] and after infusion the inhibition can be prolonged. The outcome of patients sedated with etomidate is worse than in those using alternative sedation, and steroid deficiency is thought to be the cause.[233] There appears to be a greater risk if the patient is suffering from septic shock,[234] which may not be ameliorated by hydrocortisone replacement therapy.

In the CNS, etomidate suppresses seizure activity; although patients may show excitatory movements not associated with cortical EEG changes suggestive of seizures. The intracranial and intraocular pressures are lowered. It is the drug of choice for patients who are undergoing emergency intubation, those who have head injuries, and those who have a compromised cardiovascular system, and it is safe for use in patients with asthma because there is no histamine release. Etomidate has the highest therapeutic index of any anesthetic agent.

Several case reports of the satisfactory use of etomidate for controlling refractory intracranial hypertension have been published; it is associated with fewer cardiovascular problems than are barbiturates. Nevertheless, caution must be taken concerning the development of a lactic acidosis due to the metabolism of propylene glycol.

There are two new etomidate analogs in the pipeline. They have been custom designed to remove the inhibition of the 11-β-hydroxylase by replacing a nitrogen with a methyl group that cannot bind to Fe.[235]

Carbo-etomidate has 11-β-hydroxylase inhibition that is 2000× less than etomidate; however, it is less water soluble and as such has a slow onset. The cardiovascular profile is similar to etomidate.

Methoxycarbonyl (MOC) etomidate is metabolized rapidly by nonspecific esterases. It has $GABA_A$ actions that are similar to those for etomidate. It also has a safe cardiovascular profile and minimal 11-β-hydroxylase inhibition. The recovery from MOC etomidate may be quicker than from its parent compound due to a combination of redistribution as well as metabolism.

Inhalational Anesthetic Agents

The inhalational agents remain the most widely used anesthetics in the operating room, although their mechanism of action is still poorly understood. The following agents are currently in clinical use: enflurane, isoflurane, sevoflurane, and desflurane. Sevoflurane and desflurane are newer agents that currently have limited use in the ICU. Isoflurane remains the most logical choice of inhalational anesthetic in the ICU based on its cost-benefit ratio. As with any drug used in the ICU, it is important to understand the pharmacology, the adverse effect profile, and, in this case, the technical aspects of delivering these agents to the patient. These drugs are all fluorinated hydrocarbons (Fig. 134.6). Except for halothane, which is no longer in common clinical use, they are ethyl-methyl esters. Each agent has different physicochemical properties that are important to its properties (Table 134.22).

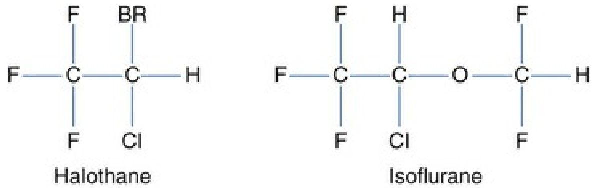

FIG. 134.6 Structures of inhalational agents.

TABLE 134.22
Vapor Characteristics

	Halothane	Isoflurane	Sevoflurane	Desflurane
Molecular weight	197.4	184.5	200	168
Saturated vapor pressure (mm Hg)	243	240	157	700
Boiling point (8°C)	50.2	48.5	58.5	22.8
Minimal alveolar concentration (%)	0.75-1.2	1.3-1.85	2.5-3	8-10
Blood/gas solubility	2.3	1.4	0.68	0.42
Oil/w% metabolized	20	0.2	3.3	0.02

Anesthesia personnel frequently use nitrous oxide as an adjunct. In some institutions it is used as the basis of a hospital pediatric procedural sedation service for children. Patients on the hospital floor undergoing minor to moderately painful procedures are mildly sedated with 50% nitrous oxide (as routinely used in pediatric dentistry); this technique has a good safety profile. A newer anesthetic agent in use in Europe is xenon. This gas has anesthetic properties with few cardiac adverse effects. It is expensive to use and requires a specialized fully closed breathing circuit to minimize the amount of gas used. The rate at which a change in inspired concentration is reflected in the brain is determined mainly by the blood/gas solubility. The more soluble the gas is in blood, the slower is the change due to the gas dissolving into the blood and reducing the partial pressure available to equilibrate with the brain. Sevoflurane and desflurane are the least soluble and therefore have the most rapid onset and offset; halothane has the slowest onset. The potency of the agents is represented by the minimal alveolar concentration (MAC). The MAC is the percentage of inhaled anesthesia agent required to prevent 50% of anesthetized patients from responding to a surgical incision. The lower the MAC, the more potent the agent. Halothane is the most potent of the agents used and desflurane is the least potent. The MAC of anesthetic agents is not constant with age. For all the agents it is highest for those aged 1 to 12 months, and the MAC falls throughout childhood to reach adult levels. Neonates show a slightly reduced MAC compared with infants. The oil/water solubility determines the degree of accumulation of the agent within the body fat stores. A highly fat-soluble agent will have larger body stores; therefore recovery from the agent is delayed.

These agents all have significant effects on the cardiorespiratory systems. Although respiration can be controlled, the negative inotropic and vasodilator effects are pronounced and limit the concentrations that can be used. Halothane, the oldest of these agents, has the greatest degree of cardiac depression. Sevoflurane and desflurane have an adverse effect profile similar to that of isoflurane, except that sevoflurane is partly metabolized to a potentially toxic metabolite, compound A, from a reaction with the sodium hydroxide in the CO_2 absorbent soda lime used in anesthesia circle systems. For accumulation of compound A to be minimized in the

circuit, a fresh gas flow of greater than 2 L/m should be used. Thus sevoflurane may not be not a good choice for prolonged ICU treatment with this type of closed circuit. There are new CO_2 absorbents such as micropore that are lithium hydroxide based and do not create compound A.[236] Due to the fact that micropore also adsorbs less inhalational agent compared to the routinely used canisters, it may be a better choice for long-term use in the ICU. Desflurane has a sympathomimetic effect, especially when the concentration is abruptly increased, and significant tachycardia and hypertension can occur.

Adverse effects of halothane include hypotension, which is due to direct myocardial depression. It also causes bradycardia because of effects on the sinoatrial node and vagal stimulation. Cardiac arrhythmias may occur, most commonly junctional rhythm. Halothane also sensitizes the myocardium to catecholamines, especially when the patient is hypercapnic or hypoxic. Because these physiologic changes are common in the intensive care patient, the potential for serious interactions with halothane abound. Halothane is metabolized approximately 20% by the liver, and a trifluoroacetic metabolite may cause an immune-mediated fatal hepatitis.[237] Isoflurane causes hypotension mainly because of vasodilation, while maintaining cardiac output. Concern has been expressed about a coronary steal phenomenon occurring in which blood is diverted from a partially obstructed coronary bed served by collateral arteries, due to vasodilation. The evidence for this phenomenon is weak, however, and ischemia is probably due to hypotension rather than a true steal phenomena. Isoflurane vapor is pungent and may cause airway irritation, coughing, and laryngospasm if the patient is not adequately sedated before its use. It is only minimally metabolized (0.2%), and a hepatitis reaction is extremely unlikely.

Malignant hyperthermia is a rare reaction that may occur whenever the halogenated inhalational anesthetics or succinylcholine is given to a patient. It involves the unrestrained entry of calcium into myocytes and consequential consumption of adenosine triphosphate, resulting in metabolic failure. Hypermetabolism, manifested by increased CO_2 production, and acidosis occur. Later the body temperature rises and death from hyperkalemia occurs. Correction of blood chemistry, aggressive cooling, and the administration of dantrolene are urgently indicated.

The metabolism of all the anesthesia agents can result in the production of free fluoride ions. Concentrations of fluoride greater than 50 μmol/L can cause renal dysfunction and a reduced concentrating capacity. This risk would appear to be higher for both halothane and sevoflurane because of their more extensive metabolism. It also may be exaggerated by patients who are prescribed drugs that induce the cytochrome P-450 enzyme complex.

Inhalational agents may cause hepatotoxicity in two ways: (1) by metabolism to reactive intermediates that are directly hepatotoxic or (2) through the intermediates that form adducts to hepatic proteins. These new proteins are then recognized as foreign, and an immune response that causes hepatic injury occurs. This is thought to be the mechanism of halothane hepatitis. This form of hepatitis is most common after halothane use; even then it is rare, occurring in 1 of 100,000 cases. It is less common with isoflurane, sevoflurane, or desflurane, which are much less metabolized. This fulminant hepatic failure, which may be fatal, is most common after repeated administrations of halothane in older obese patients. The

predominance of reductive halothane pathway metabolism results in a trifluoroacetic acid metabolite that forms a hapten. Halothane hepatitis is also less common in children.

All of the inhalational agents cause cerebral vasodilation, which results in an increase in CBF (because of decoupling of the demand/flow ratio) and ICP. In pediatric patients with raised ICP, there was no difference among isoflurane, desflurane, and sevoflurane with respect to the increase in ICP and CBF.[238] In contrast, IV anesthetics maintain the demand/flow ratio, and CBF and ICP fall, with the exception of ketamine. In addition to an effect of CBF, the arterial blood pressure typically will decrease with anesthesia, and the effect on the CPP must be accounted for. In one study, the effect of the decrease in arterial pressure on CPP exceeded the effect of increasing ICP by a factor of 3.[239] With these potential effects on CBF, the use of isoflurane should be carefully considered in patients who have or are at risk of raised ICP. Nevertheless, isoflurane has been safely used in neuroanesthesia with controlled ventilation to a normal $PaCO_2$ and an inspired concentration not exceeding 1 MAC.[240]

Isoflurane has two main applications in the PICU: sedation and the management of refractory asthma. In an adult study, 40 patients[241] who received an average of 96 MAC hours of isoflurane showed hemodynamic stability, less tachyphylaxis compared with other sedative agents, and a more rapid wean from the ventilator. No evidence was found of renal or hepatic dysfunction with serum fluorides less than 50 μmol/L. In a pediatric study, 10 patients[242] who had been receiving large doses of opiates or BZDs received an average of 130 MAC hours of isoflurane. The range of use was from 1 to 30 days. Fifty percent of the patients experienced a withdrawal-like phenomenon—most commonly, those who had received more than 70 MAC hours of isoflurane. Fluoride levels also were measured, and although they were correlated with the duration of treatment, none was greater than 30 μmol/L. The highest levels were in a patient who was taking both phenytoin and phenobarbitone. Hypotension only occurred in one patient. No hepatic or renal dysfunction occurred. The withdrawal was treated with a combination of BZDs and haloperidol with good effect. Isoflurane also has been used in patients with renal dysfunction, and fluoride levels were not elevated.[243] The starting dose for sedation should be 0.5%; this dose can then be titrated to effect by the ICU team. At levels above 1.5%, other sedative agents and paralytics often are not required.

Multiple case reports of the use of inhalational agents for status asthmaticus in both adults and children have been made. Because of its speed of onset and its bronchodilation effects, isoflurane is a useful adjunct to β_2-adrenergic agonists. If no improvement occurs, or if unacceptable adverse effects occur, then its effects rapidly wane on discontinuation. Isoflurane is recommended for use because of its safer adverse effect profile. No reports of renal or hepatic dysfunction have been made despite its use for often prolonged periods. Hypotension seems to be more common in patients sedated with isoflurane; it is possibly related to increased intrathoracic pressure and the potential for greater preload reduction with vasodilation. Fluid boluses and occasionally vasopressors are often required. Because isoflurane is not an analgesic agent, opiates may be needed for painful or uncomfortable procedures. Also, when the patient is weaned off the isoflurane, additional sedatives will be required. The isoflurane should be started at 0.5% and titrated for effect; doses of up to 2.5% have been reported as safely used.[244]
